capacity for operation on the reheating cycle. All of this capacity is for operation at initial steam pressures of 550 lb per sq in. gage or higher, and 1,150,000 kw is for operation at pressures of 1200 lb per sq in. gage or higher. For approximately 80 per cent of this capacity flue-gas reheaters are used, and for the remaining capacity high-pressure steam reheaters are used. Where high-pressure steam reheaters have been used, the reheat temperature has been limited to approximately 500 F. Approximately 30 per cent of the capacity of all turbines 20,000 kw and larger placed in service and ordered since January 1, 1925, have been designed for operation on the reheating cycle.

During the past five years there has been an appreciable

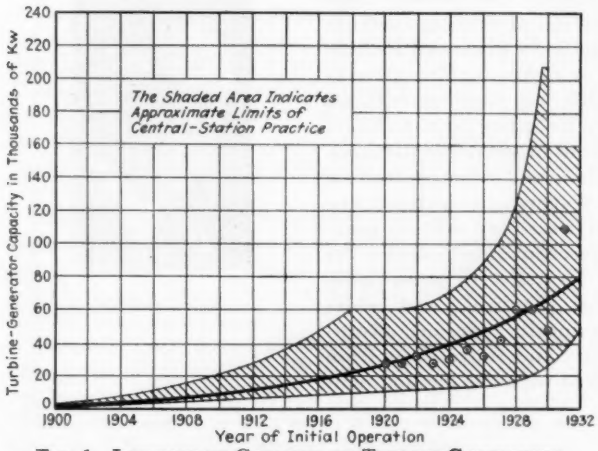

FIG. 1 INCREASE IN CAPACITY OF TURBINE-GENERATORS
(Graph shows both single and multi-cylinder units; circles are average turbine capacities from table at bottom of Fig. 5.)

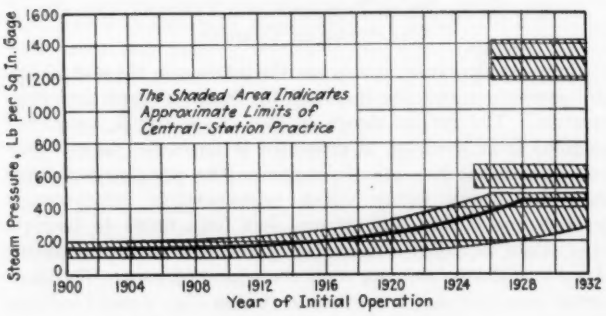

FIG. 2 INCREASE IN STEAM PRESSURE

amount of sporadic operation of large turbines with steam at temperatures from 750 to 800 F. The limit of good practice was generally considered, however, to be 750 F at the throttle. Orders were placed in 1929 with three manufacturers for turbines to operate with steam at temperatures from 800 to 850 F. An experimental installation of a 10,000-kw tandem-compound condensing turbine is now in operation with steam temperatures ranging up to 1000 F at 390 lb per sq in. gage in the Delray No. 3 Station of the Detroit Edison Company.

OPERATION ON NON-REHEAT CYCLE AT 650 LB PER SQ IN. AND 825 F

Some considerable amount of satisfactory experience has been had in the past five years with large turbines operating on a non-reheat cycle with steam delivered to the throttle at pressures 550 to 600 lb per sq in. gage and temperatures of 675 to 725 F. The percentage of moisture in the turbine exhaust is about the same for this condition as with steam delivered to the turbine throttle at 200 lb per sq in. gage and 480 F, an operating condition with which we have had considerable experience in the older stations. There has been some weight of opinion to the effect, however, that for these operating conditions the friction losses and blade erosion in the low-pressure stages, resulting from the relatively high moisture content of the steam, were too high for good practice. The raising of the steam temperature to the still higher value of 825 F makes it possible with a steam pressure of 650 lb per sq in. gage and no reheat to limit the moisture in the steam at the exhaust to the somewhat more reasonable value of approximately 12.5 per cent. This combination, having none of the complications of reheat, is a most attractive one. The new Sheboygan Station of the Wisconsin Power and Light Company and the extension to the Burlington Station of the Public Service Electric and Gas Company of New Jersey are to operate with these steam conditions. The somewhat older Michigan City Station of the Northern Indiana Public Service Company operates with steam delivered to the 60,000-kw single-cylinder turbine at 650 lb per sq in. gage and 750 F.

MULTI-STAGE FEEDWATER HEATING

One of the most striking developments is the revival and almost universal acceptance since 1924 of the practice of multi-stage

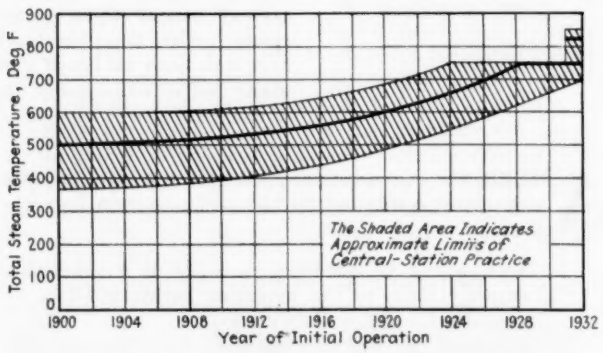

FIG. 3 INCREASE IN STEAM TEMPERATURE

feedwater heating with steam extracted from the main turbines at a number of points during its expansion. It has become common practice to extract steam from the main turbines at from three to five points and to heat the feedwater to temperatures ranging from 250 to 425 F, depending on the initial throttle steam pressure and the extent to which an economizer is depended upon to reclaim heat from the boiler-flue gases. This use of multi-stage feedwater heating places the generating station on a regenerative cycle, and insures the generation of the maximum amount of by-product electrical energy (at an overall heat rate of approximately 4200 Btu per kw-hr) from the steam extracted from the turbine at each of the different pressures. Aside from its marked effect in reducing the amount of heat rejected to the condenser circulating water and thus improving the overall station efficiency, the use of multi-stage heating of feedwater with steam extracted from the main turbines has had a most important effect, as outlined later, in making it possible to increase the maximum capacity obtainable in single-cylinder turbines.

TREND TOWARD USE OF HIGH-CAPACITY TURBINES

The marked trend toward the use of turbine-generators of higher capacity is shown by Fig. 1. It is true in general that the larger utility companies have been willing to purchase units of higher and higher capacities as soon as the manufacturers have carried their development work forward so as to permit them to build these larger machines. Table 1, showing for 14 large sta-

[a] Three 20,000-kw single-cylinder turbines were installed in 1916 and one 35,000-kw single-cylinder turbine in 1918 in the Charles R. Huntley Station.
[b] This 75,000-kw turbine took the place of the first 35,000-kw turbine installed in Cahokia Station in 1923.
[c] These two units for State Line Station will be placed in operation in 1932.

tions the units installed each year, indicates the pressure which the utilities have brought to bear on the manufacturers to develop the higher-capacity units.

Reasons for using the larger units have been lower investment per unit of installed capacity in the turbine-generator itself and in the related equipment and structures, slightly lower fuel consumption, and lower costs for operating labor and maintenance per unit of station output. The reduction in the investment per unit of installed capacity incident to the use of larger turbine-generators is in part offset by the investment for spare capacity, which is increased as the capacity of the largest turbine unit increases. A controlling reason in connection with stations built in metropolitan areas has been the desire to install the maximum possible capacity per square foot of expensive real estate.

The capacity of the largest turbine-generator installed has, as an extreme case, been as high as 120 per cent of the peak load for some of the smaller systems. For the larger systems it has been considered good practice to install units having a capacity from 10 to 25 per cent of the system peak load. Where interconnections with other systems have been adequate and the prospects have been good for rapid load growth, the tendency has been to increase the size of the generating units. An example which serves to exemplify this trend toward the use of very large units is the initial installation in the new 1200-lb Port Washington Station of the Milwaukee Electric Railway and Light Company of one 80,000-kw tandem-compound turbine-generator receiving its steam from one boiler. In few, if any, cases have the utility companies departed from the practice of providing sufficient installed generating capacity to permit carrying the peak load with the largest unit out of service, and for the larger systems conservative operating practice has required a somewhat greater margin of installed generating capacity. The law of diminishing returns is coming into play as relating to the savings in fixed charges and operating costs resulting from the use of larger generating units, and it is doubtful whether justification can be found in the near future for the use of turbine-generators appreciably in excess of 200,000 kw capacity, even on the largest systems. It is also doubtful whether many generating units of a capacity less than 30,000 kw will be installed in the future by the electric light and power companies under discussion.

Multi-Cylinder Turbines

The marked trend toward use of multi-cylinder construction for the larger turbine units is indicated by Table 1, which shows 20 cross-compound turbines,[4] 18 tandem-compound turbines, and 35 single-cylinder turbines. The advantages of multi-cylinder construction are:

1 The lower leaving loss or residual kinetic energy in the steam resulting from the use of two or more sets of low-pressure blades, each having its own exhaust to the condenser, a design feature usually embodied in multi-cylinder turbines.

2 For a cross-compound turbine, the ability to operate the high-pressure section of the turbine spindle at high speed and the low-pressure turbine spindle at lower speed. This in turn permits a smaller diameter for the high-pressure casing and in other respects results in a more favorable mechanical design.

3 Where the generator design has limited the capacity of the unit, it has been possible to raise the maximum capacity by going to cross-compound construction with two or more generators.

4 Cross-compound construction has been advantageous in permitting the installation of very large units in an existing turbine room of limited width.

5 With multi-cylinder construction only a portion of the

[4] The turbines for operation at 1200 lb per sq in. gage in the Edgar Station and the Lakeside Station are considered as compounded with the low-pressure turbines.

temperature drop, due to complete expansion of steam, occurs across each cylinder. This minimizes troubles from expansion of mechanical parts and tends to make it possible to start the turbine from a cold condition in less time.

6 Operating experience has tended to indicate that for a given capacity, with all other conditions the same, a multi-cylinder turbine will be available somewhat more hours per year than will a single-cylinder unit of the same capacity.

Single-cylinder turbine construction has, in general, the advantage of lower weight and lower investment in the turbine with its related equipment and structures for a given capacity. It tends toward more capacity per square foot of floor space in the turbine room, and undoubtedly does have an advantage in this respect over a tandem-compound machine of the same capacity. It is doubtful, however, if this advantage exists when the contrast is made between large single-cylinder turbines and large cross-compound turbines. The steeple cross-compound construction

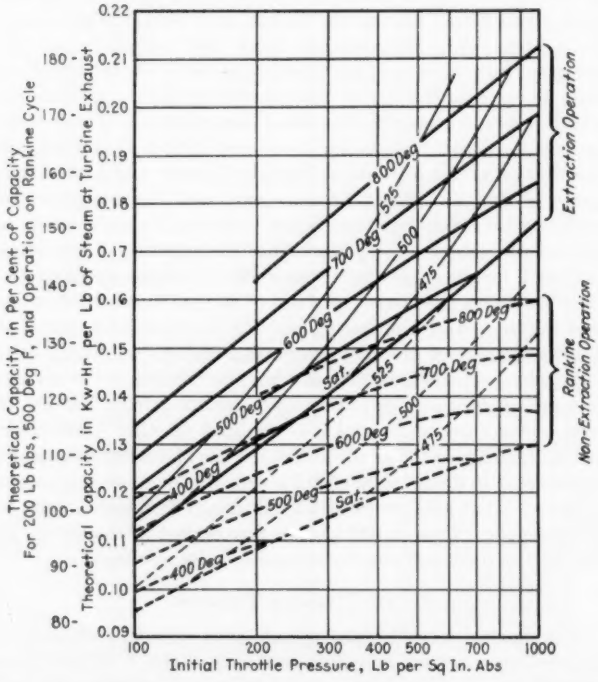

FIG. 4 THEORETICAL CAPACITIES FOR OPERATION ON EXTRACTION AND NON-EXTRACTION STEAM CYCLES AT VARYING STEAM PRESSURES AND TEMPERATURES

(Curves are for various initial total steam temperatures in deg. Fahr. as indicated. Back pressure 1 in. Hg. Specific volumes of exhaust steam in cu ft per lb may be determined by interpolation between constant volume lines. Curves are based on Goodenough, 1917.)

is extremely economical of floor space. Two 25,000-kw, two 50,000-kw, and one 110,000-kw turbines of this type are in operation at 1200 lb per sq in. gage. The high-pressure turbine and its generator are, in the case of the four smaller machines, mounted on top of the generators for the low-pressure turbines. In the case of the larger unit a 55,000-kw high-pressure turbine and its generator are mounted directly on top of the 55,000-kw low-pressure turbine and its generator.

SINGLE-CYLINDER TURBINES

Low-pressure blade areas and exhaust areas to the condenser are limited for single-cylinder machines, and this in turn either places a limit on capacity or makes it necessary to accept a higher leaving loss than that which can be rather readily obtained in a multi-cylinder design. The use of unidirectional double-flow exhaust blading, as embodied in the latest 60,000-kw turbine installed in the Lakeside Station in Milwaukee, serves to increase the low-pressure exhaust blade area which can be obtained in a single-cylinder turbine. In general it has been the experience in the United States that the manufacturers have first built machines for the higher capacities as multi-cylinder machines, and later, as they have gained more experience and have had available better materials and better shop facilities, they have built single-cylinder turbines for these same capacities.

The capacity of a steam turbine of given dimensions is limited by the ability of the last row of spindle blading to pass steam at velocities which will correspond to a reasonable leaving loss. It is not generally realized how rapidly the potential capacity of a turbine rises with increase in steam pressure, increase in steam temperature, and particularly as the low-pressure stages are unloaded and more work is shifted into the upper stages of the turbine by the extraction of steam from the main turbine for multi-stage heating of the feedwater. Fig. 4, taken from an earlier paper,[5] shows the magnitude of this effect. This increase in potential turbine capacity is much more rapid than the increase in turbine-plant efficiency. Fig. 4 shows clearly the way in which increases in steam pressure and temperature and the use of the regenerative cycle have facilitated the building of larger and larger single-cylinder turbines and have actually tended to reduce the cost of modern turbines.

There is a considerable group of engineers that have come to believe that for maximum load, wintertime conditions of operation, and a 29-in. Hg vacuum at the exhaust, a leaving loss ranging from 5 to 6 per cent of the heat available in the steam on the basis of adiabatic expansion is none too high. This is particularly true for the reason that the leaving loss for maximum-load summertime conditions of operation will, with the much lower specific steam volumes corresponding to lower vacuum for this same machine, be of the order of 2 per cent, and the average leaving loss for the year resulting from operation at partial loads and with vacuums corresponding to average circulating-water temperatures throughout the year will be of the order of 1.5 per cent. This willingness to accept turbines having a leaving loss approximately twice as great as that which has been considered in some cases to be good practice has made it possible to increase the maximum capacity of single-cylinder turbines by perhaps as much as 40 per cent. The acceptance of a higher per cent leaving loss is usually accompanied by the reduction on a per cent basis in the high-pressure packing and blade-tip leakage losses, the disk-friction losses, and other losses usually associated with the head end of the turbine, so that the decrease in overall efficiency is not as much as might be expected even for wintertime operation.[6]

During the last five years there have been installed nine turbines of 60,000 kw capacity, one of 65,000 kw capacity, five of 75,000 kw capacity, and two of 80,000 kw capacity, all single-cylinder machines. At least one of the manufacturers has expressed willingness to build single-cylinder turbines for operation at 1800 rpm and steam conditions of 650 lb per sq in. gage and 825 F at the throttle for a capacity of 100,000 kw.

No single-cylinder turbines for the expansion of steam from a pressure higher than 650 lb per sq in. gage to vacuum have been built in this country, and it appears unlikely that such machines will be built in the near future. Throttle pressures in excess of 650 lb per sq in. gage and steam temperatures in excess of 825 F seem to call for multi-cylinder construction. In general, it ap-

[5] "The Margins of Possible Improvement in the Central-Station Steam Plant," by Ernest L. Robinson, Trans. A.S.M.E., 1923, p. 644, paper no. 1913a.

[6] For a more complete discussion of the relation of leaving loss to the economic rating of a turbine, see paper "Some Recent Developments in Large Steam-Turbine Practice," by K. Baumann, Journal of The Institution of Electrical Engineers (London), June, 1921.

pears preferable to use multi-cylinder construction for the reheating cycle. There are, however, in operation in the Philo Station, the Twin Branch Station, and the Stanton Station, six 40,000-kw single-cylinder condensing turbines operating successfully on the reheating cycle.

Turbine Speeds

Most of the large turbine-generators supply power at a frequency of 60 cycles and operate at 1800 rpm. Some consideration was given a number of years ago to the construction of large turbine units for operation at 1200 rpm, but most of the recent development work has been done at 1800 rpm for the reason that this resulted in more compact and less expensive machines. Quite recently the manufacturers have developed fair-sized 3600-rpm turbine-generators.[6] Three 15,000-kw single-cylinder, 3600-rpm turbines with 18,750-kva generators were placed in operation in 1930 in the Baton Rouge Station of Louisiana Steam Products, Inc. These turbines expand steam from a throttle condition of 600 lb per sq in. gage and 725 F to a pressure of 141 lb per sq in. gage at the exhaust. Two 15,000-kw tandem-compound, 3600-rpm condensing turbines with 18,750-kva generators were placed in operation in 1931 in the Bremo Station of the Virginia Public Service Company. At least one of the manufacturers is prepared to build a 3600-rpm single-cylinder turbine of 15,000 kw capacity to operate under steam conditions as high as 650 lb per sq in. gage, 825 F, 28½ in. Hg vacuum, and this same company will build a tandem-compound machine for the same steam conditions to deliver a normal capacity of 30,000 kw with overloads up to 37,500 kw. The incentive for this 3600-rpm development is lower cost and greater compactness.

Developments in Generator Design

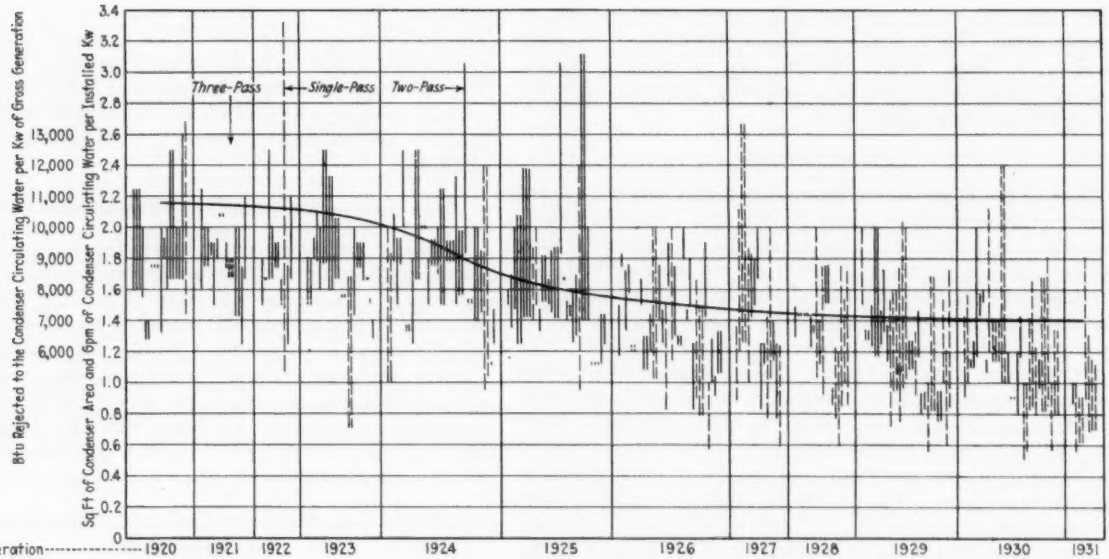
Generator design has to an appreciable extent in the past limited the capacity of turbine-generators that the manufacturers could build. At least one manufacturer is now prepared to build a 250,000-kva, 80 per cent power factor generator for operation at 1800 rpm and a 35,000-kva, 80 per cent power factor generator for 3600 rpm. The developments which have made it possible in the last seven years to quadruple the capacity of a single 1800-rpm generator constitute a separate story and have been covered by earlier papers.[7] The almost universal use since 1924 of the closed system of ventilation with finned-tube surface air coolers has had a most important influence on generator design as it has insured clean air. It has had another important influence on turbine-plant design as it has reduced the noise. The use of the closed system of ventilation has very much facilitated the rapid smothering of a fire resulting from an insulation breakdown. Generators built for capacities higher than 75,000 kva at 1800 rpm have been equipped with external ventilating fans. One manufacturer is now building a 99,000-kva generator and has indicated that he is willing to build a 150,000-kva, 1800-rpm generator with internal fans. The use of hydrogen for cooling generators would permit of still higher capacities. Several large turbine-generators have been built with provision for future use of hydrogen cooling, but none are now in operation with that type of cooling. A number of the larger generators are designed for 22,000 v. Six generators ranging from 83,333 kva to 166,667 kva have been built with double windings, three of these generators being wound for 22,000 v. The higher voltage and the double-winding feature make the problem of generator switching somewhat easier. An alternate solution is the use of an auto-transformer connected solidly to the generator leads.

It would appear that the manufacturers have caught up by their development work with the desires of the utility companies and are now prepared to build any capacity of turbine-generator that we may reasonably expect can be justified by economic studies.

Operation of Generators as Synchronous Condensers

Provision has been made in many stations for uncoupling the generators from the turbines and operating them as synchronous condensers. This procedure makes it possible, during the time when the turbine is being overhauled, to carry a substantial block of reactive kva on its generator, leaving the capacity of the other turbine-generators available for carrying true power load. It is also advantageous to operate the generators at load centers as synchronous condensers on systems that have large amounts of water power available for transmission into these load centers at certain seasons of the year.

Obtaining the Maximum Capacity Inherent in Turbine-Generators



As operating engineers have more fully appreciated the fact that for most stations the fixed charges allocated to each kw-hr of output are appreciably more than the fuel cost, they have striven to reduce the fixed charges by planning operations so as to require less reserve capacity, while still providing adequate protection for the load, and in addition they have attempted to more effectively use all the capacity inherent in the equipment. It has been found in a number of cases that from 10 to 20 per cent of capacity in excess of the normal rating was available in both the turbine and the generator, even for summertime conditions of operation. In many such cases the turbines have been rated up to higher capacities for normal operation.

The peak load for the large systems usually occurs late in November or during December. For a typical case the power factor at the time of the peak load is 92 per cent or higher. Circulating water for the generator air coolers and the condenser is at a temperature of 45 F or less. This set of operating conditions makes available at the time of the system peak 5 per cent more turbine capacity and at least 25 per cent more generator capacity than for August operation with a system power factor of 85 per cent. In some cases operating engineers have availed themselves of at least a part of this surplus generator capacity by shutting off steam to the high-pressure feedwater heaters at the time of the system peak load and sending this steam on through the turbine to the condenser. In order to carry out such a procedure, it is necessary to have sufficient boiler-plant capacity to carry the increased load at somewhat reduced efficiency. Operating engineers are very generally using temperature recorders as guides in determining safe loads that can be carried on the generators. Surplus generator capacity for wintertime operation at the high power factor coincident with the system peak load is now being taken into account by designing engineers in proportioning the relative capacities of the turbine, the generator, and the boiler plant.

The lighting load is of such magnitude in certain of the systems serving metropolitan centers that the peak loads occurring as the result of thunderstorms in the summer present a difficult operating problem, especially since they may occur when one or more turbine units are being overhauled. In such cases generators and surface condensers of more liberal design are being installed in order to provide the required amount of summertime capacity.

It has been found advantageous in some stations to make the necessary changes in physical equipment to permit of using the

FIG. 5 DESIGN CHARACTERISTICS OF SURFACE CONDENSER INSTALLATIONS FOR TURBINES OF 20,000 KW AND LARGER

(Graph covers approximately 90 per cent of all installations. Curve shows trend of design and operating practice for heat rejected to the condenser circulating water. Each line, representing one condenser installation, indicates by point at lower end "Sq ft of area per kw of gross generation," and by point at its upper end "Gallons per minute of circulating water per kw of gross generation." The installations for each year are plotted in the order of turbine efficiencies, those for the larger and more efficient turbines being placed to the right.)

additional capacity inherent in the very liberally designed low-pressure ends of the older turbines. New generators were installed and the four 25,000-kw turbines in the West End Station in Cincinnati were modified so as to increase their normal capacity to 36,000 kw each. The two 45,000-kw tandem-compound turbines in the Columbia Station below Cincinnati were converted to cross-compound machines by the installation of new high-pressure turbine-generators and their capacities increased to 63,000 kw each.[8]

NINE TURBINES IN THREE STATIONS HAVE THE SAME CHARACTERISTICS

The turbine plant of the Trenton Channel Station of the Detroit Edison Company is a rather interesting contrast to the diversified practice shown in Table 1. There are installed in this station six 50,000-kw, 1200 rpm single-cylinder turbines. Two machines of the same characteristics are installed in the Delray No. 3 Station, and another machine of the same characteristics is installed in the Marysville Station of the same company. The turbine spindles, the generator fields, and the other principal parts of these nine turbines are exactly interchangeable. The use of the spare turbine spindle which has been provided has, in a number of cases, very much shortened the time of an enforced outage due to turbine-spindle trouble. One of the 50,000-kw turbines is able to carry approximately 9 per cent of the maximum system peak of the Detroit Edison Company.

[8] For more complete discussion of work done in West End and Columbia Stations see discussion by E. S. Fields, p. 1120, vol. 48, Transactions American Institute of Electrical Engineers.

MISCELLANEOUS TURBINE DEVELOPMENTS

Other important developments in turbine practice in this country have been the very general use of water-sealed glands with resulting elimination of condensation in the wintertime on the ceiling of the turbine room; the development of speedier governor gear which will prevent the speed of the turbine from rising to a point where the overspeed trip will operate on loss of load by the generator; the almost complete elimination of lateral vibration of turbine wheels as a cause of turbine troubles; the rather extensive use of a vacuum trip attachment on the turbine throttle as a substitute for an atmospheric relief valve on the condenser; and the use of multi-valve construction so as to give good light-load efficiency on the very large turbines.

TIME REQUIRED FOR STARTING AND LOADING TURBINE-GENERATORS

The time required for bringing turbines of 20,000 kw capacity and larger from a cold condition up to synchronous speed varies from 30 to 180 min, and the rate at which load is applied varies from 1000 kw to 3000 kw per min. Representative practice for a 50,000-kw single-cylinder turbine would require almost two hours for warming up, bringing up to speed, and applying the rated load. Operating engineers seldom consider it to be good practice to operate large turbine-generators at less than 20 per cent of their rated capacity. Special provision can, however, be made on machines to be operated in parallel with water-power plants for the bypassing of sufficient steam around the governor valves to permit of keeping the turbine spindle cool, and under these conditions the turbine may be operated at appreciably lower

loads. The provision of a turning gear which will permit of rotating the turbine spindle at a speed of from 1 to 25 rpm keeps the turbine spindle straight and reduces the time required for starting. It has been considered good operating practice in a number of stations to close the stop valve in the turbine lead and open a valve in a vent connection between the stop valve and the throttle valve in order to definitely prohibit the leakage of steam into the turbine while it is not in service. This aids quick starting. The measures which most effectively facilitate quick starting are the use of steam at low temperatures and perhaps the adoption of a turbine of multi-cylinder design. One of these measures tends, however, to increase the fuel consumption, and the other tends to increase the fixed charges per unit of station output. The solution adopted, therefore, must be a compromise.

Condenser Installations

The broad trends in the design of surface-condenser installations for turbine plants are shown by Fig. 5. The importance of delivering feedwater having a minimum content of solids to the boilers has almost entirely eliminated the use of jet condensers, and not more than six or eight turbines of 20,000 kw capacity or higher, installed since 1920, have been so equipped. Surface condensers have increased in size as the turbines have increased in capacity, but the increase has not been nearly in proportion. The use of higher initial steam pressures and temperatures, reheating, extraction of steam from the turbine at a number of points for heating feedwater on the regenerative cycle, and an increase in the Rankine cycle efficiency ratio (the efficiency of converting heat available in the steam into electrical energy) have all contributed, as shown by Fig. 5, to decrease the amount of heat rejected to the condenser circulating water for each kw-hr generated. This rejected heat has, on an average, over a period of the last 12 years, been decreased from about 10,800 Btu to about 7000 Btu per kw-hr of gross generation. The area of condensing surface has, however, on the average decreased from about 1.6 sq ft in 1920 to 0.98 sq ft per kw of turbine capacity installed in 1930, and the amount of condenser circulating water used has decreased from 2.0 gpm to 1.44 gpm per kw of turbine capacity. For the eight large units operated initially in 1931, an average of 0.71 sq ft of condensing area was installed and 1.15 gpm of condensing water circulated per kw of turbine capacity. The use of single-pass condensers has increased very fast.

Much worth-while improvement in condenser design, based on thoroughgoing research work, has been accomplished. The use of better tube arrangements which insure steam penetration to all parts of the tube bank, the continuous scavenging of non-condensable vapors, and low-pressure drop from turbine exhaust to air-pump suction; the use of more effective air coolers usually external to the condenser shell; higher water velocities of the order of 7 to 8 fps through the tubes; the rather extensive use of $^{7}/_{8}$ in. and $^{3}/_{4}$ in. diameter condenser tubes rather than 1 in. o.d. tubes, as was conventional practice prior to 1924, and the use of more efficient steam-jet air-removal pumps have all contributed to improve surface-condenser performance. It has been demonstrated[9] that a 30,000-sq ft condenser of modern design can give the same overall performance as a 50,000-sq ft condenser typical of good design practice in 1919, serving a duplicate turbine and supplied with the same amount and quality of circulating water. More efficient and more frequent cleaning of condensers, facilities for the removal of debris from the inlet tube sheet while the unit is in service, divided water-box construction where there is much debris in the circulating water, and more careful safeguarding against air leakage into the condenser have all had their part in maintaining good surface-condenser performance. All of these improvements in design and operating practice have fallen somewhat short of making it possible, with the modern condensers of reduced surface operating with the much smaller amounts of circulating water per kw, to maintain as high vacuums as with the installations typical of 1920 practice. The acceptance of somewhat lower vacuums justified by the accompanying reduction in investment in the condenser and its related equipment is indicative of the careful proportioning which in recent years has entered more fully into power-station design.

The combined effects of higher initial steam pressures and temperatures, the use of the regenerative cycle, and the rather general

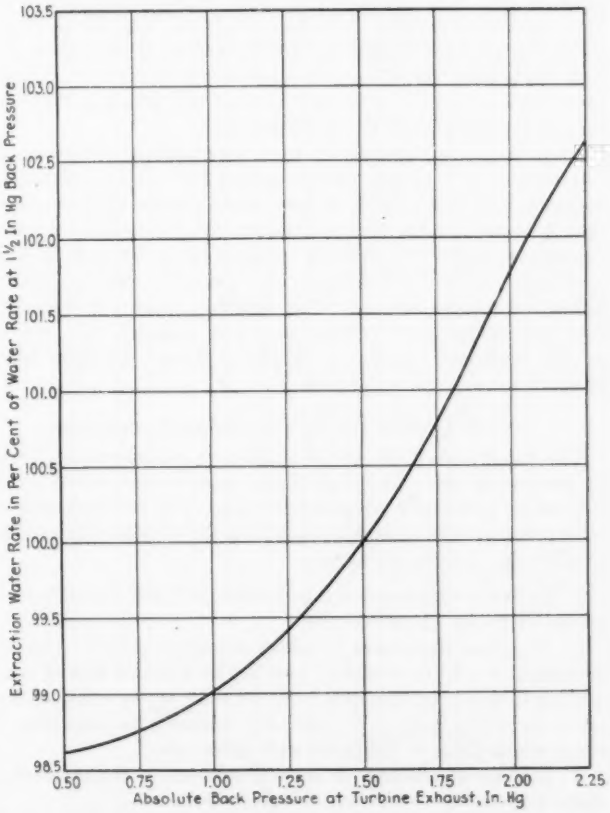

Fig. 6 Water-Rate Characteristics of a Modern Turbine at Its Maximum Rated Output

(Showing effect of relatively high steam pressure and temperature, reheating, use of regenerative cycle, and high leaving loss on the ability of the turbine to avail itself of beneficial effects of high vacuums.)

acceptance of a leaving loss of 5 to 6 per cent at maximum load and 29 in. vacuum have resulted in the shape of the overall turbine water-rate curve on an extraction basis being about as shown by Fig. 6, with the turbine rated at its proper economic capacity. Such a turbine, having but little ability at maximum output to avail itself of the beneficial effects of vacuums higher than 28.5 in. Hg, does not require nearly so large a surface condenser as would a non-extraction-type turbine of the same capacity designed for lower steam pressure and temperature and for a lower leaving loss. It develops, therefore, that the acceptance of higher leaving loss results in a substantial reduction in the investment in the condensing installation as well as in the turbine. Fig. 6 shows a reduction at full load of only 1.4 per cent in the water rate incident to an improvement in vacuum from 28.5 in. to 29.5 in. Hg. However, this same turbine at 70 per cent of its maximum rated output will for the same improvement in vacuum

[9] "Some Results of Condenser Operation," by Edwin B. Ricketts, research engineer, New York Edison Company; paper presented before American Society of Mechanical Engineers, December, 1926.

show a decrease of approximately 3.6 per cent in water rate and at 40 per cent of its maximum output a reduction of approximately 8 per cent in water rate for the same improvement in vacuum. This emphasizes the importance of condenser installations which by reason of low air leakage, efficient air pumps and air coolers, and high maintained water velocities can at partial loads maintain very high vacuums.

The trend toward the use of less surface per kw of installed turbine capacity has appreciably simplified what would otherwise have been a most difficult design problem for large turbine installations. It should not be inferred, however, that the size of condenser shells has borne a direct relation to the installed tube surface. In order to provide for adequate penetration of the steam to all parts of the tube bank, it has been necessary to provide some form of differential tube spacing or its equivalent, and this in turn has reduced the space factor (ratio of total tube cross-sectional area to total tube-sheet area), which in turn increases the diameter of the condenser shell.

From two to eight condensers have been installed to serve each of a number of the large cross-compound and tandem-compound turbines, and in a number of cases these condensers have been closely coupled to the turbine exhaust with the condenser tubes placed vertically. The present trend seems to be back to conventional practice with a horizontal condenser placed directly below the turbine exhaust. Ten turbines, ranging in capacity from 105,000 kw to 165,000 kw, have been installed, each served by one horizontal condenser. Eight of these condensers were designed for a single water pass.

Trend Toward Use of Single-Pass Condensers

The trend toward the use of single-pass condensers has been an interesting one. The four design factors which have made it possible appreciably to reduce the amount of surface required to absorb a certain amount of heat from the turbine exhaust are, in the order of their importance:

1 Better arrangement of tube surface, insuring that effective work will be done by each tube.

2 The use of high water velocities through the tubes. If good performance is to be obtained, then for each square foot of condensing surface approximately 0.005 kw must be expended on the job of scrubbing down to a reasonable thickness the dead film of water which clings to the inside wall of the tube.

3 The use of efficient air coolers, external to the condenser shell.

4 The use of smaller diameter tubes.

As designers have availed themselves of these factors, whether in two-pass or single-pass designs, there has been marked improvement in the effectiveness of the condenser, and later designs have been laid out with less surface to perform the same duty. With relatively less total surface and the use of tubes of smaller diameter and greater length, it has been found readily possible to arrange the surface for a single water pass, hold the water velocity through the tubes up to approximately 8 fps, and still not have the total circulating water exceed the amount which, for maximum load conditions, will correspond to a temperature rise of from 12 to 15 F, which in general has been found to result in a proper economic balance between pumping power, investment in circulating water tunnels and piping, and the steam consumption of the main turbines. The use of condenser shells of relatively smaller diameter with tubes up to 30 ft in length has, for the larger turbines, very much facilitated the design of the foundations which support the machines and has, in addition, resulted in condensers having appreciably lower cost for the shells, the tube sheets, and support plates.

For two-pass condensers the difficult problem is to insure that each tube will absorb its proportional amount of heat. For single-pass condensers the problem of longitudinal distribution of steam becomes difficult, particularly where very long tubes are used. Means have been devised, however, to insure that a proportionately larger amount of steam will be delivered to the cold end of the single-pass condenser.

Another interesting design trend is that toward the use of tubes rolled into the tube sheets at both ends. This feature reduces leakage and also tends to reduce the investment. A large percentage of all condenser installations in the United States have cast-iron shells and water boxes and brass tube sheets. The pressure to reduce investment has resulted in some of the newer installations being made with welded steel shells and steel tube sheets. It seems probable that this trend will continue at least as relating to the use of welded steel shells.

Deterioration of Condensing Equipment

The problem of slowing up the rate of deterioration of condensing equipment is a most difficult one, especially as the sources of condenser circulating water are becoming increasingly contaminated with sewage and industrial waste. It is fairly general practice to use Admiralty condenser tubes of No. 18 B.w.g. thickness for all installations with salt or brackish water, and Admiralty tubing is being used in preference to Muntz for perhaps 50 per cent of the newer installations using fresh circulating water from rivers or lakes. Corrosion of varying degrees of rapidity is encountered mainly at the inlet end of the tubes. This inlet corrosion is particularly acute for installations using salt water having a large amount of entrained air. The installation in the inlet water box of zinc, mild steel, or aluminum plates, supported by bronze bolts screwed into the tube sheet, has in many cases appreciably slowed up the corrosion. In a few cases provision has been made for the positive circulation of direct current between plates in the inlet water box and the tubes, and the results have appeared to be beneficial. The life of Admiralty tubing with salt water varies from three to seven years and probably averages nearer the lower figure. Aluminum bronze, aluminum brass, arsenical copper, and "30%-nickel–70%-copper" tubes are being experimented with and show promise of longer life where water conditions are bad. High content of entrained air in the circulating water causes rapid graphitization of cast-iron water boxes.

The use of brass and semi-steel water-box rings is being considered. There is a trend toward the use of slower-speed circulating pumps, and this, together with the installation of high-grade bronze impellers and the limiting of the suction head by setting the pumps low, is having a beneficial effect in reducing the maintenance on circulating pumps.

Chemical Treatment of Condenser Circulating Water

During the last two years provision has been made in at least 12 generating stations for the chlorination of the condenser circulating water. Chlorination is used to combat two distinct adverse conditions not usually coexistent:

1 The formation of slime on the wall of the tube, with rapid decrease of vacuum.

2 The growth of mussels on the walls of the intake and discharge circulating-water tunnels. This results in decreased water flow and fouling of the inlet tube sheet of the condenser as the mussels are dislodged and carried into the condenser.

Both of these problems are most acute in the summertime and add to the difficulties of maintaining even reasonably good vacuums with the warm circulating water. It has been demonstrated that by dosing the circulating water with chlorine for a few minutes at intervals ranging from 90 to 180 min, the forma-

tion of slime can be inhibited.[10] Conditions were favorable for the formation of slime from the circulating water taken from the Illinois River for the Powerton Station at Pekin, Ill. Fig. 7, contrasting a year's operation without chlorination of condenser circulating water with another year's operation during which circulating water was chlorinated for the condenser of a 55,000-kw turbine in this station, shows that with chlorination the performance of the condenser can be made to approach very closely that corresponding to a 100 per cent clean condition. Prior to the installation of chlorinating equipment the condenser tubes were scoured twice a day during the summer months by the injection of sand into the water box, and rubber plugs were shot through the condenser tubes whenever the unit was removed from service. These methods of cleaning the condenser have now been largely discontinued.[11] The proportion of chlorine required to be fed in at the screen well to accomplish this purpose is exceedingly small. While available data on mussel extermination are less decisive, results which have been reported are encouraging.

The chemical treatment of condenser circulating water bids fair to eliminate almost entirely the two filthiest jobs in the power station, the cleaning of the condensers and of the tunnels, and in addition it holds promise of very much reducing the outage time for the main turbines incident to performing this work. It is possible that, as additional experience is gained, appreciable savings will be effected in new stations by designing the circulating-water tunnels for higher water velocities on the basis of the knowledge that the tunnels can be maintained in a clean condition by the intermittent chlorination of the circulating water.

Condenser Auxiliaries

Steam-jet air-removal pumps are being used almost universally. Their compactness and low cost and the ability to absorb conveniently the latent heat of the steam used into the feedwater heating cycle have commended them in spite of their relative inefficiency when contrasted to slow-speed, motor-driven, rotative dry vacuum pumps.

Condensate pumps are usually designed to pump the condensate through at least one low-pressure extraction heater into an elevated surge tank or a combined deaerator, extraction heater, and surge tank. In most modern installations both condensate pump glands are under the pressure of the discharge from the first stage in order to avoid air leakage into the condensate. It is almost universal practice to install two condensate pumps for each turbine, one being held in reserve. Opinion is divided as to whether variable-speed drive should be provided for the condensate pumps.

The trend is toward the use of relatively slow-speed horizontal circulating pumps having efficiencies up to 85 per cent. It is fairly general practice to install two circulating pumps for each main turbine, their combined capacity being used for normal operation, but the capacity of one pump being sufficient for maximum load operation with some sacrifice in vacuum. Opinion is divided as to the necessity of variable-speed drive for the circulating pumps.

It appears that the trend with modern installations is or will be toward the maintained circulation, except for very light loads coincident with injection-water temperatures below 40 F, of an amount of circulating water which will correspond to water velocities through the tubes of from 7 to 8 fps.

[10] The original development work was done in the Crawford Avenue Station in Chicago, the Kearny Station in New Jersey, and the Northport Station on Long Island.

[11] For a more complete description, refer to article entitled "Chlorine Treatment of River Water at Powerton Station," by K. E. Stoll, Results Engineer, Super-Power Company of Illinois, *Power*, February 2, 1932.

Cooling Towers and Spray Ponds

There are probably not more than 15 generating stations of over 10,000 kw capacity in the United States that are served by cooling towers or spray ponds. The largest of these stations is the 82,500-kw station of the Dallas Power & Light Company.

Special Problems for Ohio River Plants

Very special problems are encountered in the design of the condenser installations for some of the turbine plants built on the Ohio River, the Mississippi River, and the Missouri River. In certain cases the rise in river-water level from the low flow condition to a flood condition is as much as 65 ft. The condensers and their auxiliaries in these stations are placed near the bottom of a well the floor of which is close to the extreme low-water level. In the case of the Columbia Station below Cincinnati, the floor

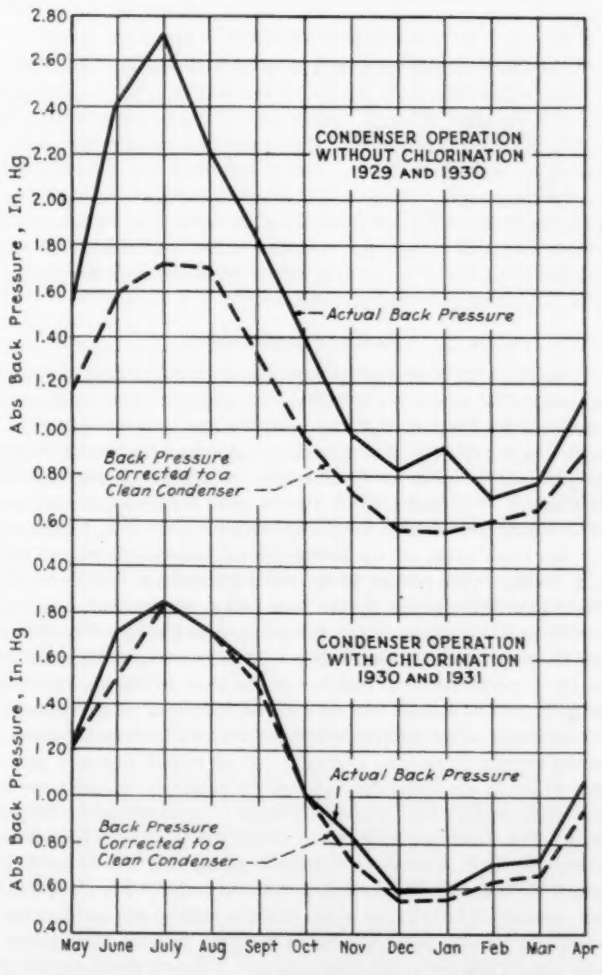

Fig. 7 Back Pressure at Exhaust of 55,000-Kw Turbine in Powerton Station
(With and without chlorination of condenser circulating water.)

of the condenser well is 86 ft below the top of the turbine platform, and the well has a diameter of 76 ft, being large enough to take the condensers and condenser auxiliaries for two 63,000-kw turbines. The very long revolving screens required for these river plants present special problems of design. In some cases special provision is made for removing debris from the space in front of the bar screens by means of a clamshell bucket. The most interesting installations of this type are the West End Station and the

Columbia Station at Cincinnati, the Northeast Station at Kansas City, Mo., and the Cahokia Station at East St. Louis, Ill.

Feedwater Heaters

The multi-stage heating of feedwater by steam extracted from the main turbines is mainly accomplished in closed feedwater heaters, which are placed as close to the turbine as possible. Vertical heaters are quite generally used in the recent installations because of their space economy. In a number of stations one open heater of the deaerating type, having a considerable amount of water-storage capacity, is placed so as to deliver water to the suction of the feed pumps. The closed feedwater heaters are designed to operate on from 3 to 10 F terminal difference, and the open feedwater heater is designed for less than 1 F terminal difference. It is general practice to cascade the drips from one heater into the next lower heater and pump the combined drips back into the feed line at either one or two points.

Evaporators

In the larger condensing stations of modern design, the make-up to the boilers runs from 0.8 to 1.5 per cent, and this make-up is usually supplied through evaporators. Fresh water is usually fed to the evaporators, and in some cases this water is first passed through a water softener in order to minimize the scale troubles in the evaporator. It is rather general practice to deliver low-pressure steam extracted from the main turbine to a single-effect evaporator and to deliver the vapor either into the next lower feedwater heater or to an evaporator condenser located just beyond the next lower extraction heater.

Boiler-Feed Pumps

Two or more boiler-feed pumps are usually grouped with and considered as a part of the turbine installation. In a number of cases the feed pumps have been selected so that one pump has sufficient capacity to handle the feedwater for a turbine of 50,000 kw and in a few cases for turbines of even larger capacity. There is a school of thought which favors more conservative practice in connection with this most important auxiliary, as evidenced by the installation of six motor-driven boiler-feed pumps and four steam-driven pumps to serve the 208,000-kw turbine in the State Line Station and by the installation of nine motor-driven pumps and two steam-driven pumps to serve the two 105,000-kw turbines in the Powerton Station. It is rather general practice to group moderate-sized turbines of less than 40,000 kw capacity in pairs and to install four boiler-feed pumps of equal capacity for each pair of turbines, one motor-driven and one steam-driven pump serving as reserve capacity. It is rather common practice to drive the boiler-feed pumps by means of variable-speed induction motors having a speed range of approximately 20 per cent. For steam pressures up to 650 lb per sq in., the feedwater passes through only the condensate pump and the boiler-feed pump on its way from the condenser to the boiler. For an operating pressure of 1200 lb per sq in., there is usually one and in some cases two booster pumps installed in series between the condensate pumps and the boiler-feed pumps. A recent development of interest is the use of motor-driven boiler-feed pumps of the plunger type to serve the two new 1200-lb-pressure turbines in the State Line Station.

Arrangement of Equipment

Most of the turbine plants fall into three classes, as regards the arrangement of equipment:

1 Turbines placed lengthwise in the turbine room with horizontal condensers directly beneath the turbine exhaust, the condenser tubes being at right angles to the turbine shaft. Turbines are arranged in pairs, with the throttles of No. 1 and No. 2 adjacent to each other and a common space provided for withdrawing the fields of No. 2 and No. 3 machines. Only a narrow platform is provided around the main turbine, and the turbine-room crane has direct access to the condenser water boxes and the circulating pumps. Space is provided on the condenser-room floor for the landing of parts when the turbines are dismantled.

2 Turbines are placed crosswise, and horizontal condensers are placed directly beneath the turbine exhaust, with the condenser tubes at right angles to the turbine shaft. Turbines are arranged in pairs, with a common space for each pair used for the withdrawal of condenser tubes and the installation of the condenser circulating pumps. Somewhat larger platforms are placed around the turbines, but in most cases openings are provided so that the crane has access to the condenser water boxes and the circulating pumps. Space is provided on the condenser-room floor for the landing of parts when the turbines are dismantled.

3 Where a high premium is placed on ground area, the turbines are placed crosswise in the turbine room and horizontal condensers are used with their tubes parallel to the turbine shaft. The space underneath the main generators is used for the withdrawal of condenser tubes and for the circulating pumps. The distance from center line to center line of adjacent turbines is cut down to a minimum. A continuous floor is placed at the top elevation of the turbine platform, and during dismantling turbine parts are landed in the space at the end of the generator. In order to provide space for the withdrawal of the condenser tubes, it is necessary to locate the generator air coolers, generator air ducts, and the external fans above the turbine platform. For such installations the external fans for the generators have been mounted on the two sides of the generator, at the end of the generator, or on top of the generator.

The trend of boiler-plant design has been toward more and more capacity per square foot of ground area, and the present tendency, at least for turbine units of 50,000 kw capacity and smaller, is to install one boiler per turbine. With the crosswise arrangement in the turbine room and a single row of boilers in the boiler room, the space requirements for boilers and turbines substantially match each other. It is believed that, even for very large turbine units and compact layouts used where ground area is at a premium, it will still be possible with a crosswise turbine-plant layout to match boiler capacity against turbine capacity by installing two boilers per turbine, one on either side of a central firing aisle, which will be parallel to the turbine room.

Centralized Control

In some of the newer stations of moderate capacity up to 100,000 kw, provision has been made for centralizing the control for two turbine-generators, together with their related boilers, and the electrical control for outgoing transmission lines at a point in the auxiliary bay between the boilers and the turbines. The wall between the turbines and the boilers is omitted so that the operator may be able to see the principal pieces of equipment from the control station.

Turbine-Generator Foundations

Both structural steel and reinforced concrete have been used for turbine supports. For the larger turbines it is usually necessary to use foundation supports of greater height in order to provide space for the condenser and the piping. This makes the problems of design more difficult.

Structural-steel supports have been most generally used where very compact layouts have made it necessary to conserve as much space as possible for the installation of the condenser and piping. This is particularly true where the condenser is installed with the tubes parallel to the turbine shaft.

Perhaps the most important factor contributing to the success-

ful performance of turbine foundations, whether of steel or reinforced concrete, is the stiffness of the individual members and the rigidity of the support as a whole. While increased mass in the support aids of itself in resisting tendencies to vibrate, and therefore the more massive reinforced concrete supports are inherently advantageous, it has been found that by limiting the deflections of individual members to low values and providing adequate bracing, satisfactory supports can be constructed of either steel or concrete. With steel supports mass and stiffness are provided by filling between steel girders with concrete wherever practicable. Generally the supports are entirely independent from the building framing. In a number of New York stations, however, the floors around the units have been framed from building columns directly to steel turbine supports with satisfactory results. This procedure conserves space below the turbine-operating platform by eliminating auxiliary floor-supporting columns or deep girders. With this construction the floor framing is usually not considered as bracing the turbine support, which is designed as though entirely independent, and special care is taken to make the support itself rigid to insure that vibration will not be transmitted to the building frame.

There have perhaps been more cases of troublesome vibration in resonance with the turbine in structural-steel supports than for those constructed of reinforced concrete. Most cases of troublesome vibration can be traced to a lack of stiffness in the support rather than to the material of which it was constructed, and usually it is found to be due to unbalance of the turbine-generator rather than to inadequacy of the support itself.

General Acceptance of Motor Drives for Turbine-Plant Auxiliaries

There has been a very definite trend toward the use of motor drives for the turbine-plant auxiliaries, the one major exception being the 280,000-kw East River Station of the New York Edison Company, in which case it was considered that extreme measures were justified for the insurance of reliability. In most cases 2300-v induction motors have been used for the drive of the condensate pumps, the circulating pumps, and the boiler-feed pumps. The incentive of simpler, less expensive, and more compact control equipment of the air-break type has dictated the use of 440-v and 550-v motors in several of the recent installations. Direct-current motors have been used in the stations of the Detroit Edison Company.

Protection of Power Supply for Auxiliaries

A 10-sec interruption in power supply for the circulating pumps or a 60-sec interruption for the condensate pumps and boiler-feed pumps is apt to cause an outage of turbines or a curtailment of their output. It becomes extremely important, therefore, to safeguard the continuity of power supply to these auxiliaries.

Five solutions of this problem have been quite generally used:

1 The power supply for the essential auxiliaries is taken through one or more banks of transformers from the main-station bus. This solution is particularly applicable where the station is interconnected with several other stations and there is fair assurance that at least one of the several sources of power supply will always be available. Facilities must be provided for quickly switching the station auxiliaries to any one of these sources of power supply, and it is to be noted, especially ni connection with the circulating pumps, that but little time is available to make a changeover. It is rather common practice to divide the essential auxiliaries into two groups, each deriving its power supply from a separate source, thus insuring that the loss of one source of power supply will shut down only one of the two circulating pumps for each machine.

2 The essential auxiliaries for each turbine are supplied with power from a bank of transformers connected directly to the generator leads. Where generator reactors or step-up transformers are installed in the generator leads, the voltage at which power is supplied to the essential auxiliaries still holds up fairly well, even though a short circuit occurs on an outgoing line, on the main-station bus, or in one of the main generators.

3 The essential auxiliaries for each turbine receive their power supply from a smaller generator directly coupled to the main generator. These smaller generators for auxiliary power supply are not operated in parallel, and the auxiliary generator for each turbine and its group of essential auxiliaries constitute a system that is independent of troubles on the main-station bus and independent of troubles with the auxiliaries of any of the other machines. In order to provide for starting and the possibility that any one of the auxiliary generators may be temporarily crippled, provision is made for an alternate source of power supply from the transformers that supply power to the non-essential auxiliaries or from a house turbine.

4 The power supply for the essential auxiliaries is taken from an auxiliary generator, which is driven either by means of a condensing turbine or by a turbine which supplies steam for feedwater heating. In the latter case, it is necessary to interconnect the auxiliary generator with the main-station bus in order to provide for interchange of power. This solution of using a separate auxiliary generator driven by means of a condensing turbine has the operating advantages of the auxiliary shaft generator and the further advantage of being free from troubles incident to a drop in system frequency. It involves, however, a rather considerable investment and at least some sacrifice in overall station efficiency.

5 A combination of the first and the fourth solutions may be obtained by installing a turbine-driven auxiliary generator, which is available to pick up the auxiliary load quickly in the event of trouble on the main-station bus bars. In some cases these auxiliary generators spin normally as synchronous condensers with no steam passing through the auxiliary turbines, and in other cases they stand normally at rest, but are of such design that they can be started and the load be applied within 15 sec. These auxiliary turbines usually exhaust to atmosphere.

The problem of protecting the power supply for the essential auxiliaries in the boiler plant is of similar nature and is directly related to turbine-plant problems. It has, however, certain special aspects, the discussion of which is not within the scope of this paper.

It is probable that at least 60 per cent of the large turbine-generators installed have direct-connected exciters.

Reliability of Turbine-Generators

For the last ten years an intensive and critical study has been carried on by the Prime Movers Committee of the National Electric Light Association, having to do with the extent, the causes, and the means of prevention of outages of turbine-generators.[12]

The results of this study over the 10-year period are summarized in Table 2. The most interesting things to note in this table are that the total average outage for the turbine-generator has decreased from 15.3 per cent of the total hours in 1922 to 8.37 per cent in 1931 and that there has been a substantial reduction in the outage hours for the turbine and for the generator, but only slight indication as yet of a reduction in the outage hours incident to condenser trouble.

[12] For the details of this study, which has been comprehensive, refer to the reports of the Prime Movers Committee, National Electric Light Association, for 1922 and 1923 and the Serial Reports of the Turbine Subcommittee of the Prime Movers Committee for 1924, 1927, 1929, 1930, 1931, and 1932.

NOTE: "Service demand factor" is the ratio of the demand hours to the period hours, the demand being either because of need for capacity or for best system economy. "Service demand availability factor" is the ratio of the service hours to the demand hours. "Unit capacity factor" is the ratio of the kw-hr generated to the product of the unit rating and the period hours. "Unit output factor" is the ratio of the kw-hr generated to the product of the unit rating and the service hours. "Service hours factor" is the ratio of the service hours to the period hours. The several "outage factors" and "Reserve hours factor" are the ratio of the hours in question to the total period hours.

As the records of turbine-generator outages have been analyzed year by year, predominant weaknesses have been located and steps have been taken to eliminate them. The manufacturing companies have carried on extensive research work, and by the use of better materials and the better application of these materials, have eliminated causes of trouble. Almost every case of field trouble has been the subject of critical study by the engineers of the manufacturing companies. The operating engineers have studied the problem from the standpoint of developing better operating methods, detecting trouble in its early stages and avoiding its further development by preventive maintenance work, and by carefully scheduling a large percentage of the outages of the turbine-generator unit for times when the unit is not needed for capacity or for best system efficiency.

The development of machines that involve new design problems has almost always been accompanied by increased outages, and as field experience has been gained the outages have been materially reduced. In 1925 the turbine-outage factor for the seven turbines, operating at a pressure of approximately 550 lb per sq in. gage, was 14.75 per cent. This factor was reduced to 5.6 per cent in 1928, 4.76 per cent in 1929, and 4.32 per cent in 1930. The turbine-outage factor for turbines of 50,000 kw capacity and higher in 1928 was 8.05 per cent. This factor was reduced to 7.04 per cent in 1929 and to 5.17 per cent in 1930. The turbine-outage factor for 1930 for ten turbines operating at a pressure of approximately 1200 lb was 10.68 per cent. It is to be expected that the outages in connection with the 1200-lb turbines will be progressively reduced as additional field experience is gained.

The most encouraging aspect of the turbine record for 1930 was that the record for the 16 machines which saw their first year of operation in 1930 shows a total outage, chargeable to all causes, of 5.06 per cent, which is in contrast to an average outage of 9.17 per cent for the 324 machines reported upon. For every other year during which the records have been analyzed, the outages for the new machines having their first year of operation have always been appreciably higher than the average by reason of the troubles encountered during the early months of operation. This highly satisfactory record for 1930 gives indication that the manufacturers are now producing machines that may reasonably be expected to operate satisfactorily from the day they go into service.

The effective work that the operating engineers have done is evidenced by the fact that they were able to schedule 72 per cent of the total outages for the turbines during 1930 for such times as operation of the machines was not required.

Remaining Causes of Turbine-Generator Outages

Certain important factors remain that will continue to cause outages of turbine-generator units, as follows:

1 Breaking of turbine blades after they have become weakened through vibration. We believe that as a result of research work being done by the manufacturers the extent of this trouble is decreasing year by year.

2 Erosion of low-pressure blading. Although minimized to some extent by the use of better blade materials and the bleeding out of some water with steam extracted for the low-pressure heater, this trouble continues to be a serious one, and we must face periodic replacement of low-pressure blading.

3 Deposits of solid matter on turbine blades. For large turbines operating on high load factor, the loss in capacity may be as much as 6 per cent in three months from this cause. One solution is to wash the turbine by the injection of water sprayed into the steam lead while the turbine is in operation, but the fundamentally correct solution is a reduction, by use of corrective measures, of the amount of moisture and the solids carried over from the boiler with the steam.

4 Condenser-tube corrosion. The use of the best materials available for condenser tubes and of methods for inhibiting corrosion gives promise of reducing outages chargeable to this cause.

5 Condenser cleaning. This problem has become more acute year by year because of the increasing contamination of condenser circulating water. It will not be surprising, however, if as a result of the chlorination of condenser circulating water the condenser outage factor is reduced to as low as 1.5 per cent of the hours in the year.

6 Generator outage. It is believed that the extensive use of the closed system of ventilation for generators from 1923 on has been very largely responsible for the reduction in generator outages. There is now a trend toward a slightly increased outage chargeable to the generator, and this no doubt is due to the use of larger machines. This is evidenced by the fact that the generator outage factor for machines of 50,000 kw capacity and higher for the year 1928 was 0.78 per cent, for 1929, 1.57 per cent, and for the year 1930, 2 per cent.

Trend of Station Performance

There was included as a part of the 1925 report of the Power Generation Committee of the American Institute of Electrical Engineers a curve showing the trend of performances of typical stations of 60,000 kw capacity and higher, plotted against dates of initial operation of the stations. In Fig. 8 we have reproduced this same curve and extended it to 1932 and have also shown the way in which improvements in the boiler plant and turbine plant have contributed to reduce the overall fuel consumption per kw-hr of net station send-out. The improvements in turbine plant performance have been almost entirely the result of a reduction in the amount of heat rejected to the condenser circulating water.

The curves in Fig. 8 show not the best performance that has been obtained, but rather the average performance of typical stations. The following accomplishments are indicative of the

performance that is being obtained in the most efficient stations operating at high load factors:

The 400-lb Long Beach No. 3 Station, operating on a station capacity factor of 66 per cent, had an average fuel rate during 1930 of 13,075 Btu per kw-hr of net send-out.

The 1200-lb Gilbert Station, operating on a load factor of 65 per cent, had an average fuel rate for six months of 12,536 Btu[13] per kw-hr of net send-out.

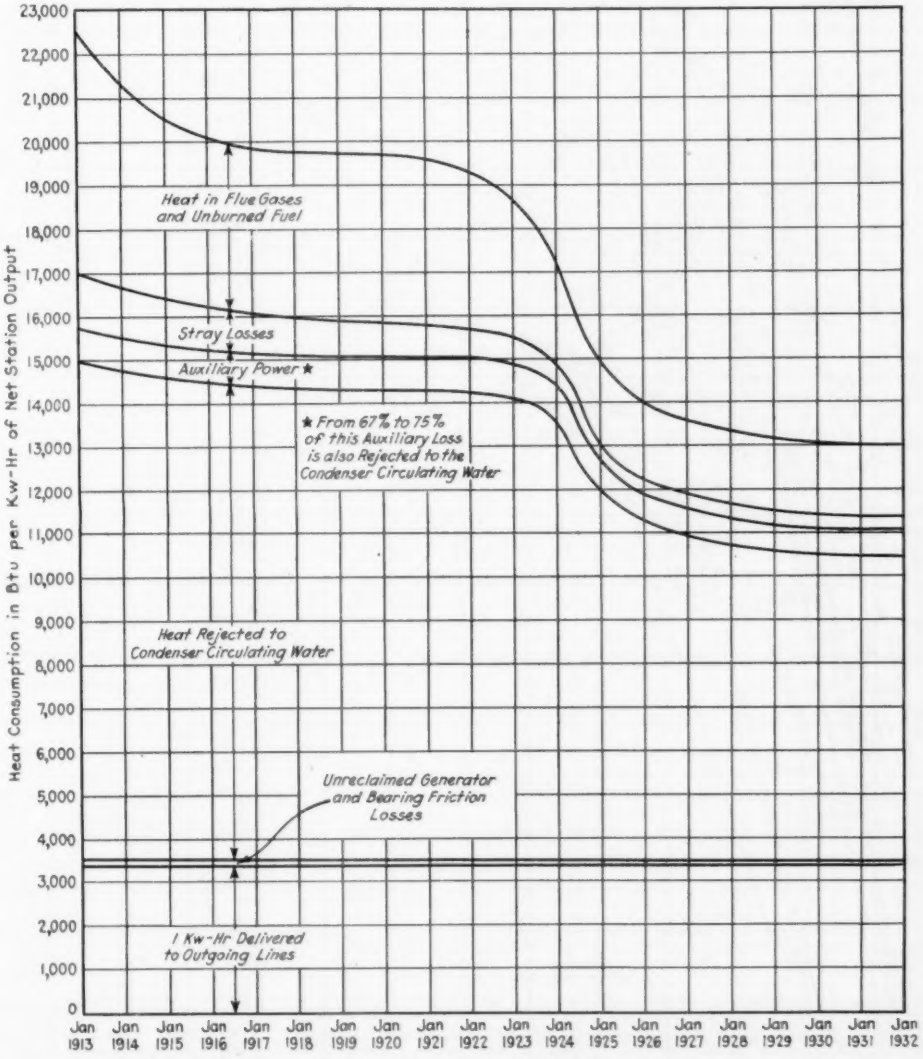

FIG. 8 PERFORMANCE OF TYPICAL STATIONS OF 60,000 KW CAPACITY AND HIGHER
(Plotted against dates of initial operation.)

The Powerton Station, operated at a steam pressure of 600 lb with reheat during 1931, with an average capacity factor of 63.8 per cent, had an average fuel rate of 12,680 Btu per kw-hr send-out, this result being accomplished with low-grade coal which averaged 10,213 Btu per lb.

The 1200-lb Deepwater Station, operating on a load factor of 81.1 per cent during 1931, had an average fuel rate of 12,050 Btu per kw-hr of net send-out.

WATER-RATE TESTS ON TURBINE-GENERATORS

A more specific review of turbine-generator performance is given in Table 3, which summarizes the results of carefully conducted water-rate tests made on 34 machines ranging from 6000 kw to 165,000 kw in capacity. Although not entirely satisfactory for the purpose, the overall Rankine cycle efficiency ratio (the efficiency of converting heat available in the steam into electrical energy delivered to the generator leads) has been found to serve most effectively as a basis of comparison for turbines operating under varying conditions as relating to steam pressure and temperatures at the throttle, back pressure at the turbine exhaust, extraction for feedwater heating, and the use of the reheating cycle.

The results of all the tests have been carefully reviewed and the average overall Rankine cycle efficiency ratios calculated on the basis of the Keenan steam tables, published in 1930 by The American Society of Mechanical Engineers. Figs. 9 and 10 show the overall Rankine cycle efficiency ratios plotted against net generator outputs. It is to be emphasized that a direct comparison cannot be made in Figs. 9 and 10 between two machines operating under widely different conditions and that this applies particularly as relating to back pressure at the turbine exhaust. Test No. 30 serves to illustrate this point, the Rankine cycle efficiency ratio for full primary-valve opening dropping off from

[13] This fuel rate is based on coal purchased at the mine and covers the difference between mine weights and plant use, which is estimated to amount to as much as 2 to 3 per cent.

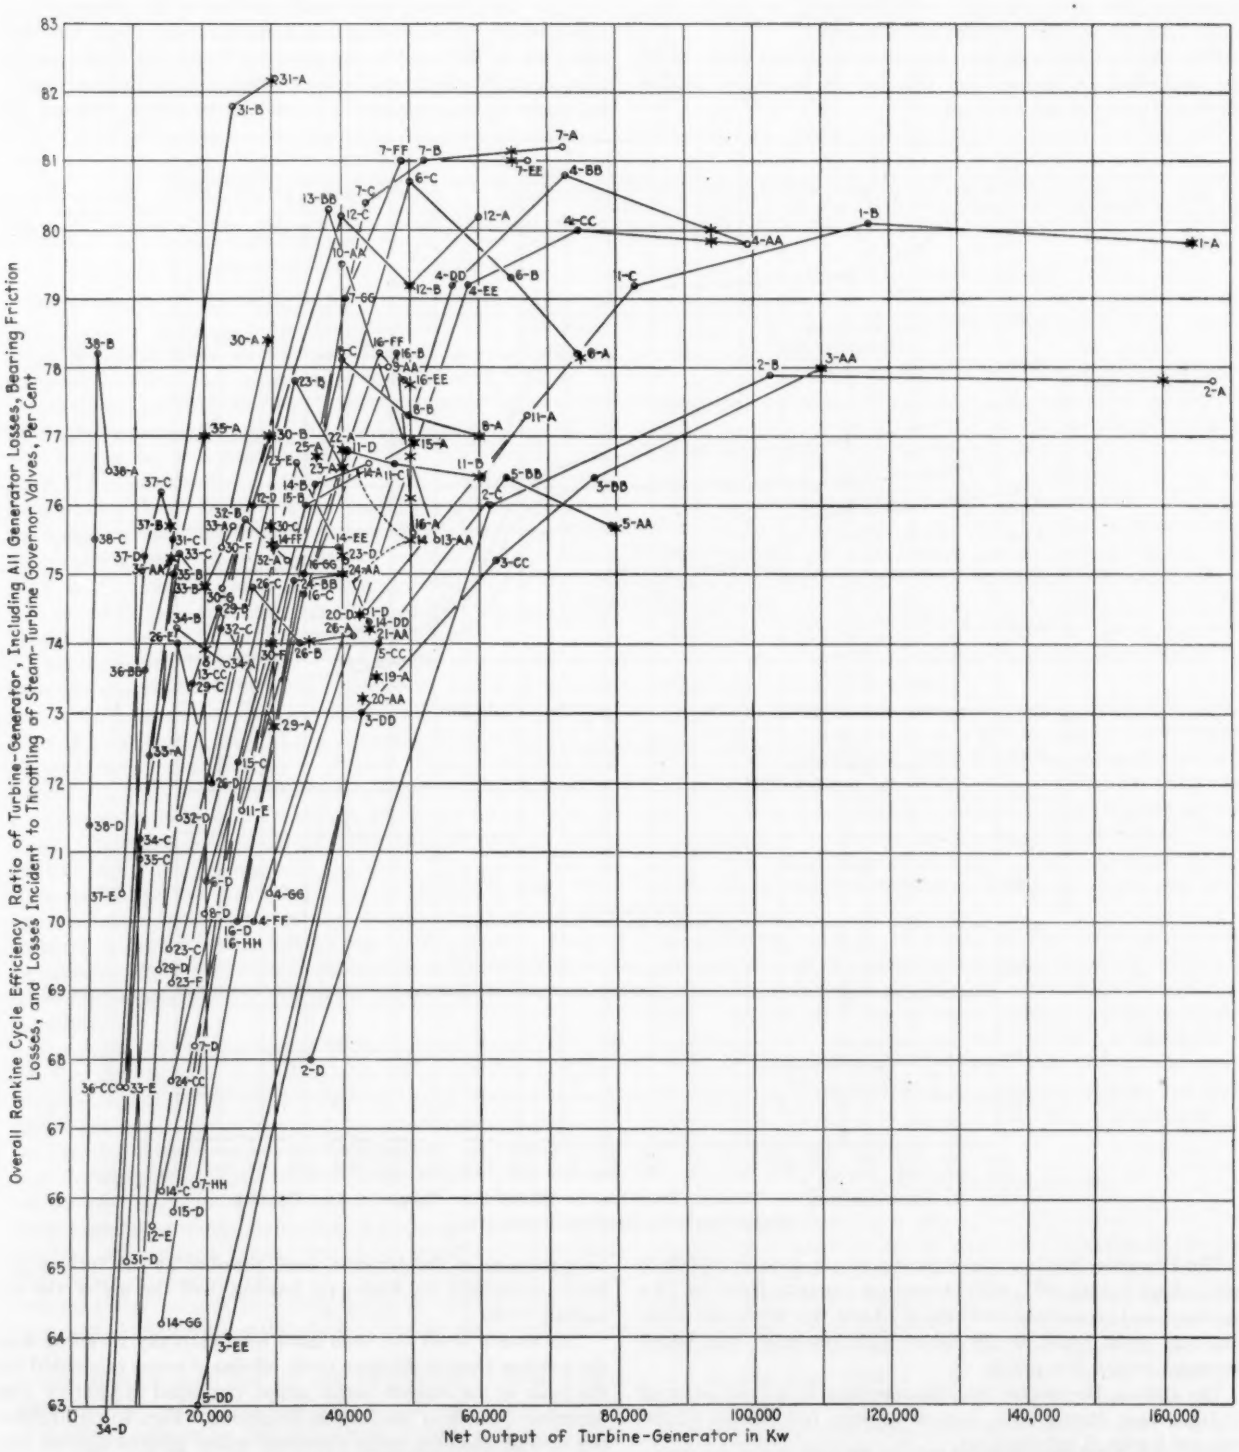

FIG. 9 TEST PERFORMANCE OF 34 TURBINE-GENERATORS RANGING IN CAPACITY FROM 6000 KW TO 165,000 KW

(Stars indicate normal rated capacity. Double letters indicate extraction tests and single letters non-extraction tests. Fine lines connect tests made at several different loads on same machine. Detail results of tests are summarized in Table 3. Also refer to Fig. 10 for large-scale graph of range from 0 to 50,000 kw.)

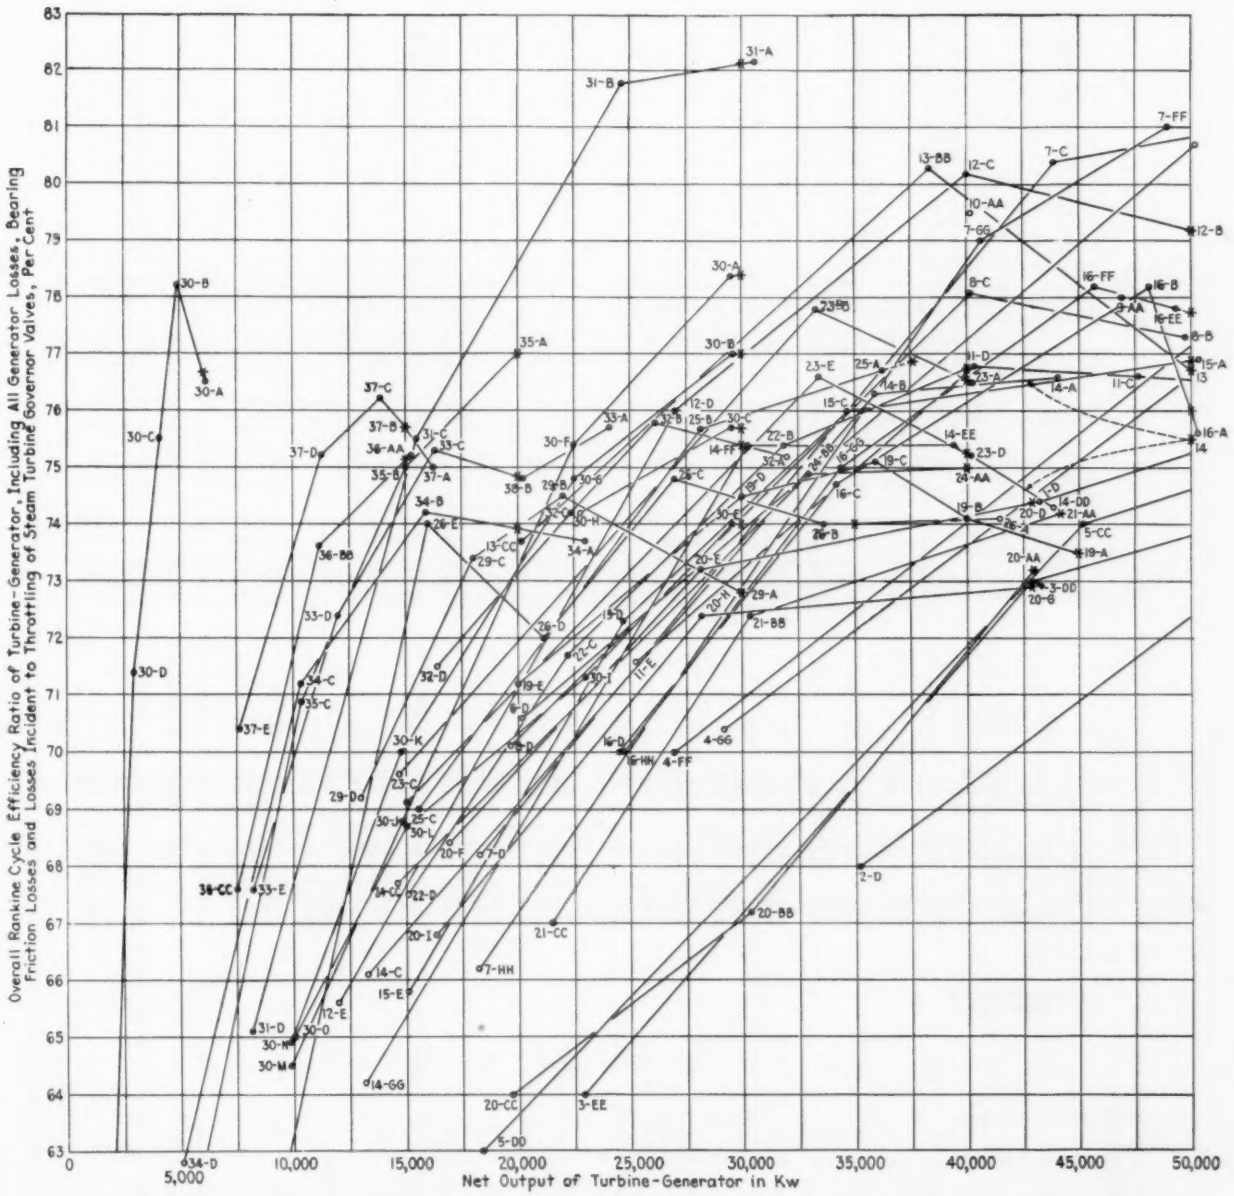

FIG. 10 TEST PERFORMANCE OF 34 TURBINE-GENERATORS RANGING IN CAPACITY FROM 6000 TO 165,000 KW.

(Stars indicate normal rated capacity. Double letters indicate extraction tests and single letters non-extraction tests. Fine lines connect tests made at several different loads on same machine. Detail results of tests are summarized in Table 3. Also refer to Fig. 9 for small-scale graph of range from 0 to 170,000 kw, which shows all of the test points.)

78.4 per cent for a back pressure of 1.505 in. Hg to 77 per cent for a back pressure of 0.987 in. Hg and to 74 per cent for a back pressure of 0.572 in. Hg. Test No. 30 was made on a turbine having a relatively low leaving loss. Tests made on a machine having a higher leaving loss would show an even more rapid decrease in Rankine cycle efficiency ratio with decrease in back pressure.

The results for each test must be interpreted in the light of the operating conditions as given in Table 3.

It is of interest to note that the Rankine cycle efficiency ratios for normal rated loads, as shown in Fig. 9, all fall within the range from 72.8 per cent to 82.2 per cent, both the maximum and minimum values occurring for 30,000-kw turbines. Maximum load tests Nos. 1-A, 2-A, 7-A, and 31-A, all made on a non-extraction basis, are fairly comparable, the back pressures ranging from 2.21 in. Hg to 2.48 in. Hg. Maximum-load tests Nos. 4-AA, 6-A, 8-A, 12-A, 16-EE, 30-A, and 38-A all show relatively good performances at somewhat lower back pressures ranging from 1.0 in. Hg to 1.58 in. Hg, and would certainly have shown somewhat higher Rankine cycle efficiency ratios had the tests been made with a back pressure of 2.25 in. Hg.

A study of Figs. 9 and 10 shows the very limited extent to which the use of very large turbines has contributed to the reduction of unit fuel consumption. The increased difficulty of fitting the larger machines to the daily load curves tends to increase the hours of light-load operation. Notwithstanding the rather marked effect which the use of from three to five governor valves has had in improving the partial-load performances of the larger turbines, their light-load performances still fall below the maximum-load performance of even the moderately efficient turbines of one-third the capacity.

No tests on turbine-generators operating on the reheating cycle were available for inclusion. It is probable that at least

[a] About. [b] Baumann multi-exhaust. [c] Except for larger generator, this unit is same as 43,750-kva unit reported upon. [d] Types of turbine construction are indicated as follows: s, single-cylinder; tc, tandem-compound; cc, cross-compound. [e] Approximate. [f] In these cases (indicated by *), the condensate temperature was not recorded, and a value has been assumed as related to the exhaust-steam temperature and the load. [g] Performance of 37,800-kw turbine is based on gross generation, which includes approximately 120 kw of excitation load.

some of the turbines operating with steam delivered to the throttle at 550 lb per sq in. gage and 725 F and reheat of the steam by flue gas to 725 F would show on test an overall Rankine cycle efficiency ratio of from 83 to 84 per cent.

The extraction of steam for the heating of feedwater tends to improve the overall Rankine cycle efficiency ratio. The accompanying trend toward the development of appreciably higher capacities from existing turbine frames resulting in higher leaving losses has largely canceled the potential improvement in Rankine cycle efficiency ratio by reason of extraction of steam for feedwater heating. The higher blade and disk friction losses and the greater blade-tip leakage losses with high-pressure steam tend to a reduction in Rankine cycle efficiency ratio, but this effect has been offset by the trend toward higher steam temperatures, with the resulting reduction in friction losses in the high-pressure section of the turbine by reason of reduced steam density and a very marked reduction in friction losses in the low-pressure blading by reason of reduced moisture content in the steam.

It should be appreciated that high overall Rankine cycle efficiency ratio is not an end in itself, but simply one of the means toward obtaining the desirable result of a low unit fuel consumption. It is relatively easy to obtain a high Rankine cycle efficiency ratio with a poor vacuum at the turbine exhaust, but the poor vacuum makes it difficult to obtain a low unit fuel consumption.

If a high Rankine cycle efficiency ratio is obtained as the result of operating the turbine at less than its maximum economic capacity or by design features which increase the time required for warming up and applying load to the turbine or which increase outage time and reduce turbine reliability, then it is easily possible that the debits will more than offset the credits.

Notes are included in the Appendix which will serve to answer most of the questions that may arise in regard to the turbine-water-rate tests and the methods used in analyzing the results of these tests.

Mercury-Vapor Installations

A 10,000-kw mercury-vapor turbine is installed in the South Meadow Station at Hartford, Conn., and two 20,000-kw mercury-vapor turbines are now being built. One of these turbines will be installed in the Kearny Station and the other in a new power station being built at Schenectady. Operation at the South Meadow Station during the 12-month period from February 4, 1930, to February 4, 1931, was very satisfactory. Since the latter date this unit has been out of service to permit of retubing the boiler and at the same time to correct an inherent defect in the design of the cores for the boiler tubes. The indications are that these mercury-vapor turbines, operating together with the steam-turbine plants which absorb the steam from the condensers for the mercury-vapor turbines, will generate energy for somewhat less than 10,000 Btu per kw-hr of net station send-out.

Standardization

As yet there has been little indication in American turbine-plant practice of any desire for or real attempt at standardization. The most interesting steps along this line have been the installation by the Detroit Edison Company of nine duplicate units of 50,000 kw capacity and the installation of six duplicate units of 40,000 kw capacity by companies associated with the American Gas & Electric Company.

It would appear that in the years immediately ahead the greatest promise for the reduction in cost of energy on the station bus lies in some measure of standardization, particularly as relating to steam conditions and the operating cycle, and in simplification of design which will result in a substantial reduction in investment.

Appendix

NOTES ON WATER-RATE TESTS ON TURBINE-GENERATORS

WITH a few exceptions the water-rate tests which are summarized in Table 3 were published in detail in the reports of the Turbine Subcommittee of the Prime Movers Committee, National Electric Light Association, for the years 1925, 1927, 1929, 1930, and 1931. There have been included, for comparison with these tests made in recent years, summaries of tests Nos. 11 and 32 made in 1916 and 1921 on the 30,000-kw and 60,000-kw cross-compound turbines in the 74th Street Station of the Interborough Rapid Transit Company. All of these tests were conducted by the operating companies.

For tests Nos. 11, 26, 31, and 35 the condensate was measured by volume in carefully calibrated tanks. For tests Nos. 16 and 25 the steam flow to the turbine was measured by flow meters, and for test No. 16 the steam flow meter was calibrated by means of a weighed water test. For test No. 4 the 94,000-kw turbine with its boilers was isolated and the feedwater going to the boilers was measured by means of venturi meters. For tests Nos. 12 and 37 methods of measurement are not reported. For the other 25 tests, among which are included the tests on a 110,000-kw turbine, a 160,000-kw turbine, and a 165,000-kw turbine, the condensate from the main condensers was weighed.

For tests Nos. 3 and 5 the condensate from the extraction heaters was measured by volume in carefully calibrated tanks. For the other extraction tests the steam delivered to each of the feedwater heaters was computed from a knowledge of the weight of water passing through the heater, the temperatures of the water at the inlet and outlet from the heater, the pressure of the steam as extracted from the turbine, the temperature of the heater drips, and the heat content released by drips cascaded into the heater under consideration from other heaters. For the purpose of these computations in most cases the heat content of the steam extracted from the turbine was estimated from expansion curves furnished by the manufacturers for each different load at which a test was made. The quality of the extracted steam in the superheat zone was checked by the measurement of temperature at the extraction point.

Each test was from one to three hours' duration, and sufficient time was allowed between tests to permit of stable conditions being established after a change in load, before starting the next test.

In practically all cases the water as actually weighed was corrected for changes in level in the condenser hot well, the surge tank, and the deaerator; the condenser leakage was checked and a correction was made if necessary; and corrections were made so as to exclude the low-pressure gland-seal leakage water and the condensate from the inter- and after-condensers of the steam-jet air-removal pumps from the condensate as weighed and charged to the turbine. The indications are that in no case was the steam for the steam-jet air-removal pumps charged to the turbine and that in every case the steam going to the high-pressure packing was charged to the turbine. In some cases the leak-off from the high-pressure packing was expanded through the low-pressure stages of the turbine. In certain cases this leak-off steam was exhausted to atmosphere or to the condenser, and in some of these cases, as for example test No. 30, a correction was made for the power that would have been generated if this steam had been expanded through the low-pressure stages of the turbine.

With the exception of tests Nos. 12, 19, and 29, actual test values of steam consumption are recorded in Table 3. For these three tests the actual test values have been corrected to standard throttle steam conditions, and for test No. 12 the tested steam consumption has been corrected to a back-pressure of 1 in. Hg at the turbine exhaust.

With one exception, the excitation current and the power for driving the generator fans are deducted from gross generation to arrive at the net output on which the performance is based. The performance for test No. 25 is based on gross generation, which includes excitation. In no case was the power for driving the condenser auxiliaries deducted in arriving at net output.

The average overall Rankine cycle efficiency ratio has been calculated in every case on the basis of an equivalent of 3412 Btu per kw-hr of net output at the generator leads, the steam pressure and temperature at the inlet to the turbine throttle, the steam pressure at the turbine exhaust, the steam pressures at the several extraction openings from the turbine, the assumption that all steam (both that extracted from the several stages of the turbine and that which passes to the condenser) is expanded on the same average overall Rankine efficiency ratio, and the use of the Keenan steam tables. The assumption of a constant efficiency for all stages of the turbine is known to be incorrect, but the extent to which this incorrect assumption affects the end results is negligible. In general, it is true for most turbines that the efficiency of the high-pressure stages is relatively low, the efficiency of the intermediate-pressure stages very high, and the efficiency of the low-pressure stages in the moisture zone somewhat lower. In general, it is true, at least for the larger turbines, that the steam extracted for feedwater heating is expanded on a higher average overall Rankine cycle efficiency ratio than the steam which goes to the condenser. As an exception the Rankine cycle efficiency ratio for test No. 36 has been calculated on the basis of the pressures at which extracted steam is delivered to the feedwater heaters, the pressure drop through the piping being charged to the turbine.

The Btu per kw-hr of net output for non-extraction tests, as given in Table 3, is based on the water rate, the heat content of the steam corresponding to the pressure and temperature ahead of the turbine throttle, and the heat content of the condensate as it leaves the condenser hot well, the heat contents being based on the Keenan steam tables. In cases where the condensate temperature was not recorded, a value has been assumed as related to the exhaust-steam temperature and the load, and in these cases the value of the condensate temperature recorded in Table 3 has been distinguished by an asterisk (*). It is to be appreciated that the values of Btu per kw-hr given in Table 3 for non-extraction tests are of somewhat academic interest. In many cases the turbines, though tested on a non-extraction basis, are actually operated normally on an extraction cycle, with an appreciably lower overall heat rate. In other cases the turbines in some of the older stations are normally operated on a non-extraction basis, but steam for a single stage of feedwater heating is expanded through moderately efficient turbines, which results in a somewhat reduced overall unit heat rate for the turbine plant.

The heat rate in Btu per kw-hr of net output would, for an extraction test in which the weight of water returned to the boilers is the same as the weight of steam delivered to the turbine throttle, be calculated in a very simple manner on the basis of the throttle water rate and the heat contents of steam at the throttle and feedwater at the outlet of the high-pressure heater. In the case of the partial-load test, particularly, it is quite often true that the weight of water returned to the boilers from the high-pressure heater is not the same as the weight of steam delivered to the turbine throttle during the period of the test. Correction must be made for the greater or lesser amount of heat that is delivered to the turbine throttle for use in heating feedwater, and correction must also be made in such cases for heat in the form of hot water stored in or withdrawn from the surge tank and deaerator during the period of the test. Another complication entered into the extraction tests Nos. 20 and 21; a small portion of the steam used for heating the feedwater was taken from auxiliary turbines. In order to make corrections for conditions such as those described, one must have a very thorough knowledge of all the details of the test. It was, for this reason, considered wise to accept and record in Table 3 the heat rates from the original test reports for all extraction tests, even though it was apparent that in a number of cases they were based on either Marks and Davis' or Goodenough's steam tables. It is probable that in many cases the heat rates would have been from 0.5 to 0.8 per cent higher than the values given in Table 3 if they had been calculated on the basis of the Keenan steam tables. It is to be clearly understood that though the heat rates recorded in Table 3 for the extraction tests are taken from the original test reports, the Rankine cycle efficiency ratios recorded have in every case been calculated on the basis of the Keenan steam tables. It is true in a number of cases that minor errors may have entered in, due to the fact that the quantities of extracted steam have been calculated on the basis of the older steam tables. It is believed, however, that these errors are not important as affecting the final results.

In connection with a number of turbine-generators on which extraction tests were run, provision was made for reclaiming in the condensate the heat losses from the generator air coolers, the turbine oil coolers, and the inter- and after-condensers for the steam-jet air pumps. This heat is accepted as a gift and goes to reduce somewhat the overall heat rate.

The designation in Table 3 of "Number of admission valves open" must be considered as rough. In most cases an even number, such as 2, may be taken as a fairly clear indication that the primary and secondary valves are wide open and that the tertiary valve is on the verge of opening. In a number of cases tests were made with the valves blocked in a fixed position.

In some cases the back pressure at the turbine exhaust was held constant for all loads by bleeding air into the air-pump suction for partial-load operation. In most cases, however, the tests were made with the lowest back pressure available and there was a progressive reduction in back pressure as the load decreased.

Discussion

A. G. CHRISTIE.[14] The paper presents such complete data that little is left for discussion. The purpose of adding a stage of reheating is to decrease the per cent of moisture at exhaust and thereby lessen blade erosion, which is frequently serious. A recent study made under the writer's direction indicates that the moisture content of the steam at the last row of blades is generally 1 per cent greater than usually assumed and may be even worse with turbines having high leaving losses. Data are at hand based upon careful tests indicating a comparatively small withdrawal of moisture at bleeders. A study of steam flow by means of polarized light now in progress at Johns Hopkins University indicates that the droplets formed by condensation are extremely small and do not appear to grow appreciably in size as condensation proceeds. It does not seem probable that these will be separated out in the moving blades by centrifugal force, and hence they can be removed only to a comparatively small extent at bleeder points.

On the third page the authors indicate that 200,000 kw will probably prove the largest economic size of turbine. It is always dangerous to predict turbine sizes. The writer recalls that 20 years ago one of the leading power engineers stated that no conceivable justification could be made in the future for a turbine exceeding 25,000 kw capacity.

The authors present good arguments for the more extended use of multi-cylinder turbines. When the advantages are better understood, there will undoubtedly be more two-cylinder 3600-rpm units installed in sizes up to 40,000 kw.

On the fourth page the discussion of the influence and importance of leaving losses on single-cylinder turbines is well presented. Engineers must become more familiar with the effect of leaving loss upon turbine economy and more particularly upon the economic capacity of the casing.

One criticism might be offered of the authors' use of "per cent" to express leaving losses. This refers to a certain per cent of the total adiabatic heat drop, which may vary by 100 or more Btu under different steam conditions. Also, when a stage of reheating is used, to what heat drop is the leaving loss referred? In the writer's opinion engineers should adopt the practice of

[14] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

expressing leaving losses in Btu per pound of steam to exhaust, which signifies a definite value in every case and also indicates a fixed leaving velocity from the blades.

The paragraph on the fifth page covering turbine speeds omits reference to the 15,000-kw, 3600-rpm single-cylinder Parsons turbine that has been in operation for several years at the Municipal Power Plant, Regina, Sask. This was designed for 400 lb gage, 750 F, and 29 in. vacuum. Two years ago C. A. Parsons & Co. submitted proposals for the Municipal Plant, Edmonton, Alta., for single-cylinder 3600-rpm turbines of 20,000 and 25,000 kw. capacity.

On the sixth page reference is made to the nine duplicate units in the Detroit Edison system. While this duplication has certain advantages, no attempt is made to apply the economic gains in turbine construction and operation since the first of these units was designed nearly a decade ago.

The authors stress the decrease in heat to the condenser per kilowatt output which results partly from increased heat drop and partly from bleeding. The problem before engineers is to develop an economic use for great quantities of heat at comparatively low temperatures and further reduce this loss to condensers. The Germans are using some of this steam to heat greenhouses. A study of Fig. 8 indicates that further hope for decreased heat consumption lies in either the reduction of the loss of heat in flue gases or in the heat to the condenser. The reduction of the latter offers opportunities for much thought.

Various phases of condenser design and operation are still undergoing rapid development. Treatment of circulating water will be an important factor in the future design of many power plants. Regarding variable-speed circulating pumps, the writer has found in most cases that the operators seldom avail themselves of the speed changes, but operate at full speed. Hence in later stations constant-speed motors have been used.

There seems little practical justification for a solid wall between boiler and turbine room in a modern plant. Its omission lessens first cost. Boiler rooms are now maintained practically as clean as turbine rooms. The dust in the turbine room does little damage, with totally inclosed generators and turbine governor gear.

The writer collected performance data on 16 modern American stations for a paper prepared for the International Electrical Congress, Paris. The figures on these stations check very closely the data given by the authors on the thirteenth page, except in the case of Deepwater Station, where the performance supplied to the writer for Dec. 1, 1930, to Dec. 1, 1931, was 10,850 Btu per net kw send-out.

The authors have presented valuable data upon water-rate tests of turbo-generators. The data plotted in Figs. 9 and 10 show considerable scattering of values. This is to be expected from the facts of the case. In a paper on "Trends in Steam Turbine Development," delivered by the writer at the Fourth National Meeting of the A.S.M.E. Fuels Division at Chicago in 1931, the following statement appeared:

"Efficiency in turbines is largely a matter of price. Each manufacturer offers units which will give about the same efficiency and will sell at about the same price as those of his competitors. Turbines of higher efficiency than these commercial units can be built if one is prepared to pay the higher costs of these improved designs. Load conditions, early supercession by more modern units, changing steam conditions, low fuel costs, and other factors make it uneconomical to purchase a turbine of the highest efficiency. Nevertheless, the performance of steam turbines is being steadily bettered, and this improvement will continue."

Granted that this statement is true, one can easily understand the variations in performance noted by the authors. Their conclusion that the use of very large turbines has contributed to a very limited extent to the reduction of fuel consumption is apparently justified by the data available. However, an analysis of these large units will indicate that their capacity over most efficient load is high, which with other factors accounts for their moderate performance. There is nothing to prevent the design of units of large size for higher efficiency than at present except the matter of price.

The authors have stated turbine performance in terms of Rankine cycle efficiency ratio. The derivation of this figure for bleeder and reheating turbines presents many difficulties. It would seem best to use Keenan's "availability" as a reference base, as he outlined in his paper at the last annual meeting.[15]

This paper repays careful analysis and study. It brings American practice up-to-date and indicates trends. The profession is indebted to the authors for their care in analyzing and assembling the material at hand.

T. E. PURCELL.[16] The keynote in American steam-plant practice has been reliability and economy, but sometimes it is amazing to realize what is happening to the simplicity of design which is so important, particularly during those emergencies which arise during operation. The modern tendency seems to provide such a multiplicity of controls and regulating devices and complex arrangements of piping and equipment as to tax the utmost skill of the operator.

The trend toward higher pressures has brought into existence several schools of thought as to the most suitable operating steam pressure. We should look with regret upon such discord, for it reflects the failure of the designers to agree when evaluating the factors that determine the design pressure. Some degree of standardization in the relative arrangement of equipment in the cycle, in the methods of arriving at the various design factors, and in the methods of computing the heat cycle should tend to unite the schools and place the problem on a sound economic basis. The standardization of the 400, 600, or 1200 lb pressure of course cannot be expected, because fuel cost varies and has such a profound influence on the design. Yet it seems we could standardize on the method of determining the design element.

The selection of initial steam conditions is important also, because it in some measure determines the extent of trouble that will be experienced with moisture in the lower stages of the turbine. There is no doubt as to the seriousness of the moisture problem even at values appreciably less than the 12.5 per cent mentioned in the paper. While blade materials more resistant to moisture bombardment are being developed, it appears that the most satisfactory ultimate solution will involve the elimination of moisture as it is formed rather than the development of materials resisting its attack. The corrosion problem in idle machines is also an important one which may some day be solved by circulating heated gases through the turbines when out of service.

The combined trend toward the increase in the size of steam turbines and toward the use of higher steam temperatures has very materially increased the starting time of modern turbine-generators. The means suggested in the paper to facilitate quick starting, i.e., low temperatures and perhaps multi-cylinder design, do not appear to be the most suitable in practice. Quicker starting should be obtained preferably by developing designs that permit a rapid readjustment in temperature without thermal distortions, or by maintaining the turbine at approximately operating temperatures when out of service for short periods. We have, at the Colfax Power Station, two single-cylinder machines

[15] "A Steam Chart for Second-Law Analysis," by J. H. Keenan, presented at the Steam Table Session of the Annual Meeting, New York, N. Y., November 30 to December 4, 1931, of The American Society of Mechanical Engineers; reprinted in *Mechanical Engineering*, March, 1932, p. 195.

[16] Duquesne Light Company, Pittsburgh, Pa.

that are very sensitive to thermal distortion. Originally, the time required to start one of these machines varied between 2 to 3 hours. Since slow-turning devices have been provided, the starting time after short outages has been reduced to about 45 min.

The acceptance of the 5 to 6 per cent leaving loss for large single-cylinder machines when operating at high loads is causing erosion and vibration troubles in the condenser. While vibration troubles due to the impingement of the high-velocity exhaust steam can be corrected by changes in the design of the condenser, it is nevertheless a factor that needs to be considered simultaneously with the acceptance of high leaving losses.

The actual turbine-generator capacities, rather than the rated capacities, are used on our system when determining the machines to be operated to adequately protect the load. However, we have not as yet found it convenient or very desirable to depend upon the reserve capacity available in the turbine by shutting off steam to the high-pressure bleeder heaters. The additional generator capacity available by operating the generators at high power factors would not be considered very desirable for our system, as we find it necessary from the standpoint of system stability to limit the power factor on the generators to a maximum value of 90 per cent.

It appears that operating engineers have established even a better record than that revealed by the fact that 72 per cent of their turbine-generator maintenance during 1930 was done when operation of the machines was not required. The 72 per cent apparently includes a penalty for work done when the machines should have operated for best system economy. The major concern of the operators, however, is to schedule their maintenance work on the machines when they are not needed for capacity, important as the thermal performance of the system may be. A detailed analysis of conditions on our system disclosed that, except for short periods during forced outage, the maintenance work is so planned that it never reduces the system capacity below that needed to amply protect the load.

Interchangeability of turbine-generator parts, as for example turbine spindles, to reduce outages of the unit, is rather difficult to apply in practice, although on paper it may appear to have merit.

E. L. Robinson.[17] The authors have arrived at the conclusion that the use of large-capacity steam turbines results in a reduction of fuel consumption to only a very limited extent. The implication is clearly against the installation of large units. As a matter of fact, the Rankine cycle efficiency plays only a minor part in the reduction of heat rates, the steam conditions and the type of cycle employed being considerably more important. Furthermore, the trend toward large units has been greatly influenced by the reduced fixed charges associated with large units. This point has not been particularly emphasized by the authors.

Throughout the paper the importance of leaving loss in determining the economical size of a steam turbine is well brought out. Leaving loss is commonly computed from the total weight of steam flowing to the condenser, supposing condenser pressure to exist at the last wheel annulus. A more careful analysis shows leaving loss to be made up of a number of items, among which are the following:

1 Annulus velocity energy, less a credit for particles of condensed moisture which move with very low velocity.

2 Edge eddy losses resulting from excess velocity on account of bucket-edge thickness.

3 Pressure drop through the exhaust hood itself from the wheel to the exhaust flange of the turbine, less a credit for the corresponding reduced velocity loss at the wheel due to the smaller specific volume of the steam at that location.

4 Whirl loss due to the reaction component of velocity at other loads than that corresponding to minimum leaving loss.

5 Losses due to non-uniform velocity distribution.

Items 4 and 5 are particularly important at low-volume flows with a last-stage bucket designed for high-volume flows. Furthermore, the leaving loss may be expressed (*a*) as a per cent loss of potential heat drop in comparison with the adiabatic heat drop theoretically available or (*b*) by a smaller figure expressing the loss as a percentage of the energy at the switchboard, including the energy contributed in the high-pressure stages by extraction steam.

The authors have pointed out the danger of making comparisons without taking account of leaving losses. The writer would add that it is also misleading to make comparisons based on estimates of leaving loss computed in a variety of ways.

J. N. Landis.[18] On January 22 and May 4 of this year, respectively, the Nos. 7 and 8 units carried load for the first time. Each unit is a General Electric 160,000-kw single-generator tandem-compound machine operating at 400 lb per sq in., 730 F temperature.

Both machines are smooth-running units and have given no operating difficulties with the exception of minor oil leaks and sticky governor valves. These troubles were quickly eliminated.

A weighed-water acceptance performance test has been conducted on the No. 7 unit when operating on a bleeding cycle. The results were satisfactory, the unit bettering its performance guarantee by approximately one-half of 1 per cent throughout the load range. A check test on No. 8 turbine shows it to be very slightly better than No. 7. The heat-rate curve of the unit between 80,000 and 160,000 kw has a variation of less than 1.3 per cent of the minimum heat rate.

The two condensers that serve the units have 101,000 sq ft of condensing surface each and are the largest condensers in the world. No. 7 condenser is by Worthington and No. 8 is by Ingersoll-Rand. The two units are operating satisfactorily, and preliminary figures now available from acceptance tests show that both units perform essentially in accordance with guarantees. The No. 7 main condensate pumps have given a little trouble with thrust bearings, which has been eliminated. The No. 8 condenser gave trouble at the start with high salinity caused by the ferrules backing out of the tube sheets. It is now believed that the trouble was caused by tube vibration in local spots. The tubing in those locations has been given extra staying and the remedy seems to have been successful.

E. H. Tenney.[19] The summary of steam-turbine practice is obviously a sound interpretation of typical rather than exceptional turbine developments. Since there has been at least a temporary slowing up of station economy improvement and also because of the present necessity for limiting capital expenditures, it seems likely that many of the older plants will be rehabilitated to bring them up to standards of capacity and economy. This situation may lead to a program of station rebuilding such as was witnessed a decade and a half ago, and for that reason a few comments on the question of turbine-room rehabilitation may be of interest.

In Table 1 the authors refer to a 75,000-kw turbo-generator at the Cahokia Station which in 1929 replaced a 35,000-kw unit

[17] Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

[18] Mechanical Engineer, Brooklyn Edison Company, Brooklyn, N. Y. Assoc-Mem. A.S.M.E.

[19] Chief Engineer of Power Plants, Union Electric Light and Power Company, St. Louis, Mo. Mem. A.S.M.E.

installed in 1923. In this example of rehabilitation, advantage was taken of two developments in order to bring an older section of this plant up to date in economy and particularly in the utilization of space for greater capacity. The boilers at Cahokia were originally designed in 1923 for 12,000 Btu heat liberation per cu ft of furnace per hour. Subsequent developments in pulverized-fuel firing have made it possible to achieve heat liberations upward of 25,000 Btu. Simultaneous increase in the capacity of single-cylinder turbine units and increased effectiveness of condenser surface (as pointed out by the authors) made it possible to utilize the greater boiler steaming capacity by moving, to a standby plant, a 35,000-kw unit and installing in the same space and on the same lower foundations a 75,000-kw unit of 18 per cent better fuel economy, and at an expenditure of approximately one-third of what the additional capacity would cost in a new plant. Such correlated improvement of boiler-furnace performance and turbine capacity applies at many plants and presents a definite possibility for low-cost increase of system capacity.

JOHN H. SMITH.[20] Theoretically the process of condensation is one of unqualified simplicity. The thermal and physical laws relating thereto have long since been established and countenance no trace of the mysteries nor the attending deficiencies incident to the multiplicity of structural complications which are introduced periodically as contributions toward further development of the commercial condenser. It is but a logical deduction, therefore, to expect improved condenser performance to remain forever a function of the approach, offered by the practical condenser, toward the ideals of simplicity upon which the fundamental laws were founded.

The condensation of exhaust steam effected in a vessel sealed against atmospheric pressure is made possible by extracting the latent heat of evaporation therefrom, and during the change from the vapor state to that of a liquid, the process is accompanied by a great reduction of volume and a corresponding reduction of temperature and pressure. The greater the amount of heat extracted, the greater will be the amount condensed and the lower will be the final temperature and pressure. Obviously, all vapor will never be condensed until the pressure is reduced to zero and the temperature to absolute zero.

Thus it becomes obvious that non-condensable vapor removal from any region within a condensing chamber other than that of lowest temperature surface, and therefore lowest potential pressure, results not only in a greater ratio of water vapor per pound of air removed therefrom, but also increased air and vapor pressure, increased terminal difference, and lower vacuum at the turbine exhaust.

It is axiomatic that thermal head induces steam flow to the region of lowest temperature surface, and that pressure drop resulting therefrom limits steam flow up the point of equilibrium.

Since equilibrium will be established in the vapor circuit of any condenser, it follows that all resistance other than that resulting from direct contact between condensing surface and steam should be minimized in order to promote natural flow to the region of highest thermal head in far greater quantities than would otherwise be possible. And with non-condensable gas removal correctly provided for at the exit terminal of the streams of flow, so as not to impede their natural tendency, the condenser can be said to be operating at its natural pressure drop.

As to external air coolers, they simply extend complicated structure to another unit subject to additional air leakage, and combine with all other forms of resistance to increase turbulence, eddies, and pressure drop in the effort to control steam flow. Their principal application appears to lie in the field of deficient installations in which non-condensable vapors are incorrectly withdrawn from the condenser; that is, where condensable water vapor finds the air-pump suction without having passed completely through the tube bundle to the region of greatest condensing capacity or lowest temperature surface. A condenser design of the simplicity necessary to favor the related laws of physics, thus contributing to natural flow in establishing equilibrium, renders it quite impossible to fully utilize the thermal head, and therefore requires no such appendage as an external air cooler.

Obviously the parallel relation between the several duplicate elements insures against the sharp reduction of flow areas in the natural path of vapor flow characteristic of the converging-lane principle now in common use. A comparison of the two principles is indicated in Figs. 11 and 12.

It is apparent that the converging-lane principle, indicated in Fig. 11, is based on the erroneous fundamental assumption of equal condensation per square foot of surface, hence the area reduction between planes, and obviously therefore on the basis of vertical steam flow through the condenser. The sectioned portion between condensing elements illustrates reducing steam quantity and corresponding free-space reduction. The writer, among the early advocates of the converging-lane principle, and the inventor of many existing condensers employing it, has long since come to realize that vertical steam flow through a condenser is not desirable, nor is it possible of attainment except by the introduction of complications to structure which further increase the throttling effect resulting from such area reduction along the paths of natural flow. Thus would lines of flow approach the vertical a material distance into the condenser, as indicated by lines x_1, x_2, etc.

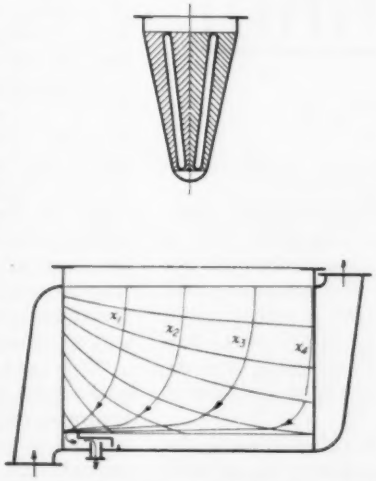

FIG. 11 CONVERGING-LANE PRINCIPLE

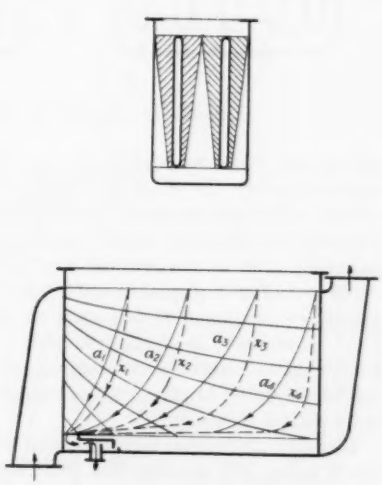

FIG. 12 PARALLEL-LANE PRINCIPLE

Full recognition of variations in heat head, and therefore variations in condensation per square foot, and also that natural pressure drop will balance the urge of steam flow to satisfy heat head far short of the potential capacity in regions of the exit terminal, has prompted the writer to provide not only the same areas characteristic of Fig. 11, but in addition thereto, the unshaded areas indicated in Fig. 12, thereby contributing to natural flow in increased amount. It is apparent that flow lines such as x_1, x_2, x_3, and x_4, characteristic of the converging-lane principle, would assume a more direct path of travel such as indicated by the full

[20] Alco Products, Inc., New York, N. Y.

lines a_1, a_2, a_3, and a_4 shown in Fig. 12, by virtue of greater flow area. This contributes to reduction of the time element and greater condensation per square foot of surface at a given pressure drop in the region of highest heat head.

Thus, it is believed, the most efficient utilization of available space provided for the installation of a condenser has only been approached, and as the economical demand for further surface increases per cubic foot of shell displacement continues, this fact becomes even more pronounced.

Neglecting adverse directional effect and high velocity of exhaust steam, it is obvious that the initially contacted surface being the most active, renders the more remote units of surface

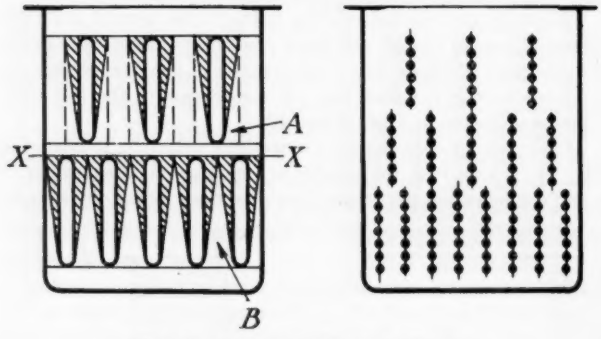

FIG. 13 INCREASED-SURFACE DESIGN

less active, thus demanding the greatest care, in distributing surface through the available volumetric space, in order to approach a balance between positional advantage and positional disadvantage of the units of surface comprising the total. This is especially true as the demand for further surface increase per cubic foot of shell displacement continues, thus demanding even greater consideration of flow areas in the path of natural vapor flow. Obviously, as steam is condensed in the top group, flow areas can be reduced accordingly in the lower group, and the logical procedure in effecting this reduction is by the addition of more surface elements.

Therefore, in further increasing surface in a given space by the use of tubes, it is evident that strict application of the parallel-lane principle throughout the tube bundle provides flow areas such as are required to promote natural flow in quantities greater than would obtain through use of the converging-lane principle. Such an arrangement is indicated in Fig. 13. Not only is a better balance between positional advantage and disadvantage of the tubes obtained, but of special importance is the assistance offered by this arrangement toward overcoming certain physical handicaps. The minimum amount of surface placed in the immediate region of the steam inlet, and therefore providing maximum free area, which can be interpreted as increasing per pound of steam in a given tube group as steam condenses, obviously provides for maximum dissipation of adverse directional effect of high-velocity steam in the sparsely populated upper group, thereby assisting in promotion of natural flow as steam passes to the lower tube groups of progressively increasing surface per cubic foot of space. Thus is the effect of tube erosion from this source minimized; and, too, since the minimum amount of condensate has the maximum distance to fall, and the maximum amount has a minimum distance to fall through the tube bundle, maintenance of free area and shell width at the bottom minimizes the detrimental effect of condensate and also reduces impedance to natural flow as compared to condensers employing the converging-lane principle, shell-width reduction, and surface disposition in the reverse order.

While it is generally recognized that, in order to improve condenser performance, steam loading on the cold end of a condenser must be increased and that on the less efficient hot end must be decreased, such as is provided for in a natural and simple manner by use of the parallel-lane principle, the use of tubes of substantial length introduces tube supports as a necessary evil. For example, it is reasonable to assume that if the tube arrangement is such as to impede natural flow of steam, the addition of tube supports will certainly add further media of prevention, thereby approaching full realization of undesirable vertical flow as the number of tube supports is increased.

Obviously, the directional effect of high-velocity steam becomes a more serious detriment to condenser performance as the condenser is sectionalized into well-defined compartments by the use of solid tube supports. Recognition of this fact has led to various methods of treating tube supports in an attempt to relieve overloaded hot sections of steam trapped therein. For example, in a previous invention the writer has cut tube supports into sections so as to provide staggered relation in various tube groups. Believed to be a step in the right direction, approximate vertical flow obtains, however, throughout the depth of any section of support plate, and in no way assists the problem of dissipating high steam velocity in the same limited sections of the upper or outer group, and contributes little toward promoting natural flow. Another method employed in an attempt to overcome these difficulties is to provide large so-called equalizing holes in the tube supports well within the tube bundle. Concentration of relief in a single large hole, or in a few smaller holes, in no way promotes balanced natural flow over the extent of the tube bundle, and certainly provides little if any relief in the section or sections between such holes and the main steam-inlet opening.

Only in the event of providing relief openings in balanced relation with every tube in the tube bundle, thus providing equal flow areas between all tube rows, is it possible to eliminate all traces of sectionalization, and thereby promote balanced natural flow throughout the tube bundle, to the maximum extent possible within the limits of practical space allowance.

While some of the existing methods of treating tube supports tend only to slightly relieve pressure in the hotter sections of the condenser, other designers have sought, through revival of various mechanical means, to control the flow of steam in predetermined amounts, and irrespective of its initial direction of flow, into the various compartments formed by tube supports. Not only have the thermal laws relating to vapor flow in a heat exchanger been wholly overlooked, evidence of which is found in the general disregard of flow areas in the natural path of travel, but by resorting to mechanical expedients in an attempt to control and redirect the flow of high-velocity steam, rather than occasion dissipation thereof within the tube bundle, it is believed that engineers have violated important physical laws as well, with the result that not only is condenser efficiency impaired, but the prime mover is prevented from driving the full benefit of the vacuum that is produced in the condenser tube bundle. For example, if it is assumed that the rate of condensation can be controlled in the various compartments by increasing resistance to flow through each succeeding hotter compartment, it can be accomplished only at the expense of turbulence and eddy losses incident to the necessity of any excess of steam reversing its initial direction of flow against the impact resulting from turbine exhaust velocities in the nature of 500 fps and above. Furthermore, the added steam load at the periphery of the cold end reflects in increased pressure drop and increased vapor content per pound of air, which of necessity must be removed by the air pump at a higher vacuum. This obvious mark of inefficiency, together with the violent turbulence and eddy losses throughout the vapor circuit resulting from attempts to control the flow of steam by introducing such artificial resistance media as throttle valves, ports, orifices, air baffles,

deflector plates, external air coolers, etc., presents a combination of factors which coincide with the effect of tube supports and an erroneous fundamental assumption relating to steam flow in defiance of the basic thermal and physical laws involved in the process of condensation.

As the name implies, air baffles are but another form of resistance to the free flow of vapors along natural lines toward regions of lowest temperature and pressure within the tube bundle. Moreover, their very location limits the effectiveness of the condensing surface they are intended to isolate, and their presence at all positively prevents any possibility of approaching balanced natural steam flow through the tube bundle at any transverse plane. Thus, the apparent wide variations in effectiveness of tubes on any horizontal plane, together with the increase of back pressure resulting from additional turbulence and eddies due to the many abrupt directional changes in the path of steam flow in gaining access to the isolated tubes and the common vapor header, render so-called air baffles not only useless, but a serious detriment to good condenser performance.

The ideal condenser consists of an infinite number of infinitely small surface elements operating in parallel, and while introduction of the second and third dimensions as applied to surface extension in a practical condenser introduces series operation as applied to a major portion of the surface elements, a logical procedure in approaching fundamentals would be to obtain as many duplicate elements transverse of the tube bundle operating in parallel as is physically possible. Mere symmetry about the vertical center line of a condenser is not sufficient to promote a balance of steam flow, but symmetry about the center lines of a multiplicity of duplicate elements affords an approach thereto. And this symmetry cannot be disturbed by introducing air baffles into the cross-section, in any attempt to approach the ideal.

It is highly desirable in any case, and especially so in the case of high-pressure steam stations, to expand the tubes into both tube sheets in order to eliminate leakage of cooling water into the condensing chamber. Moreover, where packing and ferrules are used, tube-end erosion and corrosion caused by eddies and gas liberation resulting from disturbance to stream-line flow, incident to the physical relationship between ferrules and tube ends, often result in excessive tube replacements. To minimize the effect of these maintenance difficulties, expanding tubes into both tube sheets has become a more common practice, and with it further complications to structure designed to compensate for the difference in expansion between ferrous metal shells and nonferrous metal tubes. Just as simplicity of structure is practiced as an essential procedure in giving full recognition to laws relating to steam flow, so does the writer believe the problem of compensating for expansion differentials to be equally simplified.

For example, tubes initially bowed for drainage purposes and rigidly secured at both ends are virtually self-supporting. Yet, while readily susceptible to further bowing, there is no assurance, under temperature changes, that the tubes will bow as a group in the direction prescribed by the initial bow unless so guided; hence, the principal value that can be attached to tube supports, which for this purpose can be free to move upward. Therefore, with virtually all metal not required to maintain a constant relation between tubes removed from tube supports, the weight of such tube guides is materially less than the existing forms of tube support of equal thickness and for a given number of tubes supported. And as such, this method of compensating for expansion differentials is a natural sequence to the fundamental requirements of structural simplicity.

Nor is the problem of approaching ideal conditions confined to the vapor circuit alone, for without a similar approach in the hydraulic circuit both objectives remain in a remote sphere. And in consideration of this fact, sufficient justification against mechanical manipulation of the vapor circuit is to be found, for the potential efficiency of any tube is a function of the heat-absorbing capacity of the water traversing it, which in turn is a function of water quantity; while the actual efficiency of the tube then becomes a function of the facility with which steam can contact the successively colder increments of its length.

The fundamentals of the problem of surface condenser design, therefore, appear to be clearly evident. First, the tubes of a condenser constitute the number of elements that are intended to operate in parallel, and if similarly treated, all would operate equally and in parallel. Obviously, the series function in terms of progressive condensation would be equal for all tubes, and the physical ideals of the vapor circuit would be fully provided. Second, equal distribution or circulation of water through all tubes would complete perfect balance of flow in both circuits. Obviously, neither condition can be met in practice, but a practical approach thereto is to be found in a condenser that provides physical balance, at least, between all tubes on any horizontal line across the tube bundle.

I. E. Moultrop.[21] There are now installed in the United States 2,800,000 kw of turbine-generator capacity operating on

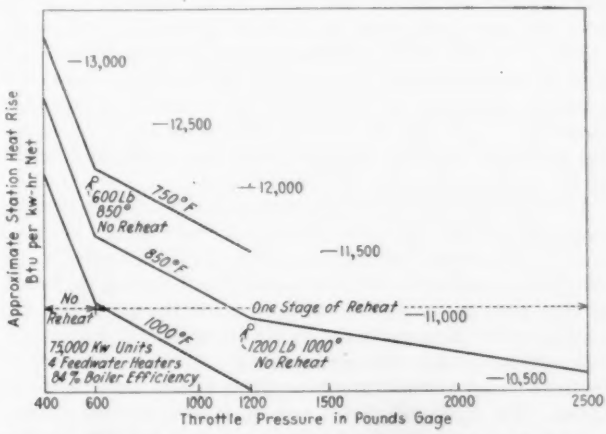

Fig. 14 Comparison of Approximate Station Heat Rates at Constant Temperature and Varying Steam Pressure

the regenerative-reheat cycle, and for approximately 80 per cent of this capacity flue-gas reheaters are used.

The May, 1932, Prime Movers Committee Report on Higher Steam Pressures and Temperatures gives some interesting data on 22 1200-lb boilers ranging in size from 150,000 to 500,000 lb per hour. This report shows that the availability of these boilers is substantially the same as for boilers operating at lower pressures, and the availability of the 1200-lb boilers installed in Milwaukee is comparable with the best performance listed in the 1931 Report of the Power Division of the A.S.M.E.

It seems to be the consensus of opinion of those who have installed and operated reheat boilers that they are just as reliable as those without reheaters.

Fig. 14 shows the approximate station heat rates at constant temperature and varying steam pressure. As one can readily see, the 600-lb, 850-deg non-reheat station will show approximately 5 per cent better station heat rate than the 400-lb, 850-deg station. But it is also a fact that the 1200-lb, 850-deg reheat station shows approximately 9 per cent better station heat rate than the 600-lb, 850-deg. non-reheat station.

The operating companies that have built 1200-lb reheat stations report that there is practically no difference in unit cost of

[21] Chief Engineer, Edison Electric Illuminating Company, Boston, Mass. Mem. A.S.M.E.

construction as compared with 400-lb non-reheat stations. In view of these facts, there seems to be no justification for the statement that the 650-lb, 825-deg station is the most attractive one.

Another important consideration in the selection of the most economical pressure and temperature is the fact that the design and manufacture of high-pressure generating equipment is in its infancy. As time goes on, designs will be improved and manufacturing methods will be changed so that we will be able to install the more economical equipment for considerably less per unit of capacity than we can today. It is necessary, however, that we go through a period of development. If we can promote this development without actual financial loss, by the use of equipment that is economically justified at its present price, we aid in the progress of the art and will reap even greater profits in the future. If we refuse to install the equipment which our engineering studies indicate is the most economical, we are seriously hindering the progress of our industry.

The paper points out that larger units reduce the unit cost of construction, but that this is partially offset by the investment in spare capacity. We should also remember that large units reduce operating labor and maintenance, and up to a rather large size improve the station heat rate. It is wondered if, in the long run, large units really do increase the investment in spare capacity. If the largest unit has a capacity of from 20 to 25 per cent of the system peak, it is believed that it actually results in a lower cost including spare capacity than if the individual units have a capacity of only 10 per cent of the system peak. The average additional capacity required due to the larger units is not great and the unit cost is considerably less.

It is very encouraging that the multi-cylinder units are showing even greater availability than the single-cylinder units. We need units of high availability which can be put on the line quickly. If the system load curves are going to continue to grow in the future as they have in the past, with sharper and sharper peaks, the need for units which can be put on the line quickly and which can pick up load quickly will become acute. It will be very wasteful to be forced to load turbines as slowly as it is necessary to do today. The multiple-cylinder turbine is probably the answer.

In its proper sphere, standardization is very desirable, but the writer questions the advisability of attempting to go very far in the standardization of station design for some time to come. The design of station equipment is going through such a radical period of development that too much standardization is likely to slow up development. If a large number of units of the same size and design are installed for a rapidly growing system, the unit cost of construction will be considerably higher and the slight advantage of a number of duplicate units will be more than offset.

If we are going to be able to take advantage of the new ideas in steam-generator design, such as the series boiler, it is necessary that we find some way to reduce condenser leakage. The condenser with tubes expanded into the tube sheets seems to offer a practical solution.

If chlorination of the circulating water will permit continuous condenser performance equal to new tube conditions, it will not only result in better station economy, but it will permit a further reduction in condenser size and a worth-while reduction in the unit cost of construction and maintenance. While the improvement shown for Powerton Station could probably never be realized by tidewater stations, nevertheless the possibilities are very much worth while.

Electrically driven auxiliaries have been adopted quite generally, but unless more satisfactory variable-speed motors and controls are produced, we can expect to see a swing back to turbine-driven auxiliaries for some of the important auxiliaries. For auxiliaries requiring large-capacity variable-speed prime movers, the turbine drive has many advantages that may even justify a slightly higher station heat rate.

M. K. Drewry.[22] The authors devote only a single statement to the new subject of turning gears. This apparatus has proved to be of considerable importance to the successful operation of two recently installed 60,000-kw units. Daily shutdown and starting of these two machines, of different manufacture, is impossible without turning gears. The first machine was

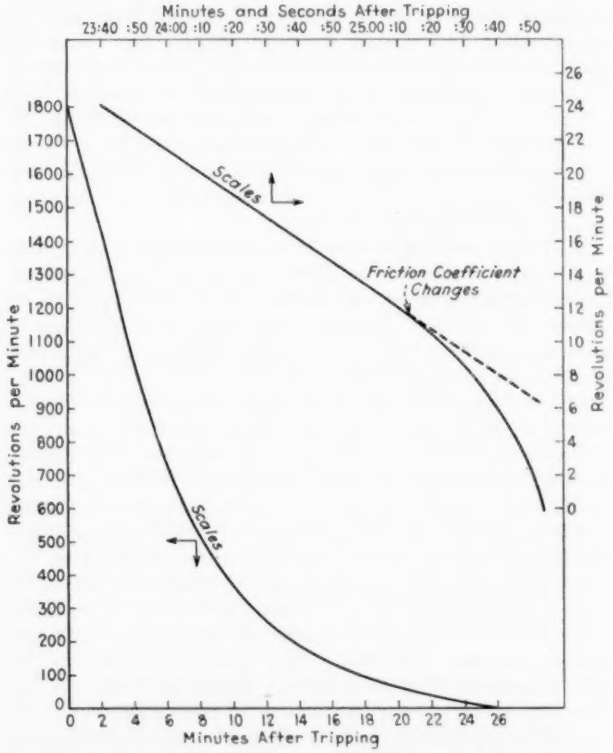

Fig. 15 Deceleration Curves of a 30,000-Kw Impulse Turbine (Zero field current. Normal operating oil temperatures.)

started only once after a short idle period without previous use of the turning gear. It was not brought into service until noon, though started early enough for forenoon loading. The second machine was installed initially without a turning gear. When started after several days' outage, no trouble was experienced, but it positively could not be used for overnight outage service. On several occasions it could not be started at all during the day that its use was desired. Turning gears on both machines have made their operation entirely satisfactory.

The spindles of both turbines are of large diameter, being of the reaction type. When at rest, considerable difference in metal temperature must occur between the top and bottom of the spindle because of its large diameter. Very slight temperature difference causes sufficient deformation to result in severe vibration when starting, and the deformation cannot be removed in a few hours of turning.

An eccentricity of 0.015 in. near the shaft seals would occur without use of the turning gears after shutdown. Two days' cooling would eliminate this bowing, as would 6 hours of turning at 25 rpm. The machines are always kept turning for 8 hours after shutdown. Approximately 6-kw input is required for 25 rpm.

[22] Assistant Chief Engineer of Power Plants, Milwaukee Electric Railway and Light Company, Milwaukee, Wis. Mem. A.S.M.E.

Fig. 15 gives data showing the importance of reasonably high turning speeds. When a typical turbine slows below approximately 10 rpm, its speed drops very rapidly, showing that lubrication changes nature. The shaft speed must be high enough to maintain oil films, or oil under high pressure must be supplied below the journals.

Authors' Closure

The discussion presented has served in the main to supplement the paper. Our purpose in presenting this paper was to give the truest possible picture of steam-turbine-plant practice in the United States. It has seemed important to present, not only the facts, but also our interpretation of the facts. It is perhaps not too unexpected that several of the engineers who have discussed the paper should question our interpretation of the facts as presented. Operating experience and the trend of design during the years immediately ahead will perhaps serve as the most effective answer to the questions which have been raised.

[Note: Discussion of this paper, jointly with that of F. W. Gardner, by M. H. Adams, Gerald Stoney, H. M. Martin, and W. F. Ryan will be found following the discussion of that paper.]

FSP-55-3b

British Practice in Steam-Turbine Design

By F. W. GARDNER,[1] NEWCASTLE-ON-TYNE, ENGLAND

This paper reviews considerations affecting steam-turbine development in England. Turbines of the size and type required for the larger central stations are covered, although description of some of the smaller plants has been included. In discussing steam conditions, attention has been confined to general tendencies. Developments in turbine practice have been influenced by the plan to link up all the power stations by an interconnecting network of transmission lines. To cope with the increased demand, new large power stations will be constructed, which will have the advantage of high load factors and favorable conditions for base-load running. Illustrations are given of types of turbines and equipment.

THE aim of this paper is to present a brief review of considerations affecting steam-turbine development in Great Britain at the present time. The subject embraces such a wide field that it is only possible here to draw attention to a few of the salient features and to indicate very briefly their influence on the progress of design. Reference has been made to a few of the problems that arise, with the knowledge that these and many similar problems are familiar to American engineers, for it is felt that they will gain rather than lose interest on that account. For the most part the paper has reference to turbines of the size and type required for the larger central stations, but a brief description of some small plants has been included to illustrate the developments at the other end of the scale. A short note dealing with condensing plants has also been included.

The many interesting developments that have taken place recently on the marine side do not come within the scope of the paper, which has been confined to features relating to land practice.

In preparing the paper, the author has drawn chiefly upon the work of the firm with which he is connected, for it is naturally of this work that he has the most detailed knowledge and experience. At the same time he has endeavored throughout to treat the subject from a general standpoint, and he gratefully acknowledges the assistance received from friends in other companies, which has helped to make the paper representative of British practice.

[1] Chief Engineer, C. A. Parsons & Co., Ltd. (Turbine Department). Mr. Gardner was born near Liverpool, England, and was educated at the King's School, Chester; was graduated in Mechanical Sciences at Cambridge University. He joined the staff of C. A. Parsons & Co. at Newcastle-on-Tyne in 1912, leaving to join the forces at the outbreak of war in 1914. Held a commission as Engineer Officer in the Naval Airship Service, becoming a Major in the Royal Air Force on the transfer of the airship personnel to the Air Force in 1918. At the end of the war he returned to the Parsons Company, becoming head of the turbine-design staff a year or two later, and was recently appointed to his present position. Mr. Gardner visited the United States and Canada in connection with the firm's business in 1930.

Contributed by the Power Division and presented at the Semi-Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

In discussing such matters as steam conditions, attention has been confined to general tendencies, and no reference has been made to experimental, specialized, or exceptional plants, though of course a number of installations in these categories exist.

INFLUENCE OF THE "GRID"

Developments in turbine practice in Great Britain during recent years have been influenced to a considerable extent by the introduction of the National Electricity Scheme, which provides for the eventual linking up of all the power stations in the country by an interconnecting network of transmission lines known as the "grid." It also provides for the erection and equipment of a number of new large central generating stations, for the extension of the larger and more efficient of the existing stations, and for the scrapping of a great number of small and inefficient stations.

At the period in 1920, when the Electricity Commissioners were appointed and given power to investigate the whole subject of electricity supply in Great Britain, the requirements both domestic and commercial were being dealt with by some 540 power stations, varying from quite small outputs up to 100,000 kw capacity. The largest individual units at that time were about 25,000 kw. These stations were variously owned by municipalities, public supply companies, or private companies, all working under statutory orders, but operating independently of each other. As a consequence of this there were wide variations in the systems of supply, each authority or company having fixed the conditions to suit the requirements of its own undertaking, with the result that there existed d-c systems at various voltages, a-c of one, two, and three phases, and frequencies ranging from 25 to 100 cycles. Each undertaking had to make its own provision for the standby and emergency plant to insure continuity of supply, though in certain areas, where conditions permitted, voluntary interconnections were made to enable some degree of interchange of supply to be arranged.

The Electricity Commissioners were given powers to control all additions to generating plant in existing power stations, and new power stations could be built only after their approval had been obtained. These powers applied only to public-service undertakings and did not cover private generating stations in factories or mills. The commissioners were also given powers to compel undertakers to install interconnecting lines to facilitate the interchange of supply. Already the number of stations in operation has been reduced to some 300, and provision is made for an eventual reduction to about half that number.

The investigations of the Electricity Commissioners and the subsequent report of the special committee under the chairmanship of Lord Weir in 1925, led to the passing of the Electricity Act of 1926, under which the Central Electricity Board was appointed to undertake the construction and operation of the grid power lines and the unification of frequency throughout the country at 50 cycles. A voltage of 132 kv has been adopted for the main transmission lines of the grid.

The central board has power to raise capital, out of which they meet the expenses incurred by the undertakers on change of frequency in their areas, where such change has been carried out under an instruction from the board. The board is paid by the Electricity Commissioners the sums required to meet interest and sinking-fund charges on the money raised for frequency-change purposes, and the Electricity Commissioners in turn make a

charge on all authorized undertakers on the basis of revenue received from the sale of electricity, other than that sold in bulk to authorized undertakers.

Developed under the long-sighted and organized policy of the commissioners, the National Electricity Scheme will undoubtedly encourage the use of electricity for all purposes, and as a result a continued increase in consumption is to be expected. To cope with the increased demand, as it arises, new large power stations will be constructed, which will have the advantage of high load factors and the conditions most favorable for base-load running. Although a considerable amount of new generating plant will thus be required to carry the load that will be available when the grid gets into full operation, the ultimate effects of the scheme will be, first, to encourage large units and eliminate small ones, and, second, to diminish the total kilowatts of new plant constructed, owing to the reduction in the amount of standby plant required. The manufacturing capacity of the turbine works in the country will therefore be much greater than will be required to meet the demand for new plant, as it is clear that much less labor, machine time, and works capacity will be employed in the building of one 50,000-kw unit than would be required for the production of, say, five 10,000-kw machines.

The demand for small units for factories and mills that generate their own power is very meager at the present time in consequence of the general trade depression by which so many industries are affected. The grid scheme is likely to reduce considerably the demand for such units in the future, as under it factories will be able to obtain very favorable rates for power supply, and electrification without capital expenditure on generating plant will become the most attractive proposition. Industrial plants that require large quantities of steam for process work will, however, be able to generate more cheaply with their own plant, and will in some cases be able to feed current into the grid.

Although the amount of water power available in Great Britain provides only a small percentage of the total requirements, hydroelectric installations are being constructed, which will take advantage of the grid lines for distribution into the general system.

Size and Type of Units

To equip the new central stations, large generating units are required—that is to say, large in comparison with the sizes previously found economic for the conditions existing in England. At the present time a number of units are in operation or under construction ranging in capacity from 50,000 to 75,000 kw. Where extensions to existing stations are carried out and where existing plant of non-standard frequency has to be replaced, units of from 15,000 to 40,000 kw capacity are usually required.

Practice in England is definitely in favor of single-line units, and all the plants now being installed are of this type. The size of unit in relation to the normal output of the station is so chosen that there does not arise the necessity for operating one section of a machine independently of another, a provision that usually has to be made where large cross-compound units are installed.

Multi-cylinder machines are general for both impulse and reaction turbines. The principle that a large number of stages with moderate steam speeds are essential for high efficiency has long been known, but has in the past been rather ignored in impulse-turbine design, where the application of partial admission encouraged the use of large wheels at the high-pressure end. Latterly, however, the manufacturers of impulse turbines have concentrated on many-stage machines. Fine diaphragm and blade clearances are as essential for efficiency as low steam velocities. This necessitates short, stiff rotors and imposes a limit on the number of wheels per cylinder. Consequently, to utilize efficiently the heat drop available with the higher steam conditions now in use, either two- or three-cylinder designs are nearly always employed.

The demand for high thermal efficiency has necessitated also the provision of large blade areas at the exhaust end to keep the leaving losses small. This has doubtless influenced the choice of rotational speeds, and up to the present single-line units of 40,000 kw and upward have all been designed for 1500 rpm. Several 30,000-kw plants at 3000 rpm with double-flow low-pressure elements are in operation, and as 3000-rpm generators can be built for much larger outputs, an extension of the size at this speed is to be expected because the manufacturing cost of the turbines is much reduced. Larger units have, in fact, been introduced on the Continent. A 3000-rpm turbine with three exhausts and the same tip speed as is used in current practice, say, 1050 fps, is capable of an output of 50,000 kw.

Present Trend in Steam Conditions

Steam Pressure. For the larger central-station plants now under construction a steam pressure of 600 to 650 lb per sq in. is being generally adopted. This applies whether reheating is employed or not, and indicates that there exists a remarkable uniformity of opinion among those responsible for the choice of steam conditions on the question of the most suitable pressure. Whereas in the past pressures have crept up gradually and by small stages, interest today is concentrated chiefly on two pressure levels at about 600 and 1200 lb per sq in. This is because the theoretical cycle efficiency is increasing fairly rapidly with the pressure up to 600 lb, but above this the efficiency curve becomes relatively flat, and the view is widely held that intermediate pressures possess to a considerable degree the limitations of the higher level, while the potential saving is too small to justify their adoption on the score of efficiency. They are found only in cases where special conditions have had to be taken into consideration, such as the power-output requirements in relation to the quantity of process steam for chemical or industrial purposes.

Among English engineers there appears to be a definite preference for the 600-lb level. Much importance is attached to securing the highest possible internal efficiency of each individual part of the plant, and this is regarded as the best method of obtaining a good overall performance, as it involves less capital expenditure than the adoption of the higher pressure. With the total temperature and other conditions kept the same, the maximum possible saving in fuel at 1200 lb, as compared to 600 lb, amounts to some 5 per cent, but this difference is easily lost unless the efficiency of the boilers, turbines, and auxiliary equipment is fully maintained.

Temperature. The generally accepted steam temperature is 800 to 850 F at the turbine stop valve. In the matter of temperature there is not really very much choice at the present time, since a fairly definite limit is set by the properties and behavior of the materials available. The strength of the usual materials of construction falls off as the temperature rises. In the past this has generally been met by designing the parts subjected to the full temperature with proportionately lower stresses so that the factors of safety have been maintained. Between 850 and 900 F, however, change in the physical properties becomes so rapid that it cannot be allowed for by design alone. Much attention is therefore being paid to the production of materials more suitable for higher temperatures and to the investigation of the properties of such materials. Designers would not, however, be justified in adopting a higher temperature for an important base-load station until a fuller knowledge is available as to the effect on these materials of prolonged exposure to high temperatures. Further, special materials are usually expensive, and even when their reliability is established the economic problem of their use has to be considered.

In connection with the problem of service at high temperatures,

interest is concentrated primarily on the creep characteristics of the material. The short-time yield, which is such an important factor in assessing the suitability of material at lower temperatures, ceases to possess much physical significance, because the amount of strain is influenced so much by the time interval during which the stress is applied. It is now generally realized that the creep limit cannot be defined as the stress below which the creep strain is zero, but that any stress will produce a slow plastic deformation. The designer has therefore to decide what rate of deformation is permissible for any particular application of his material.

The design of the high-temperature part of the boiler presents the most serious problems, but these do not come within the scope of this paper. As regards the turbines, it may be broadly stated that for cylinder castings and shaft forgings the stress must not exceed a value which will produce a creep of 10^{-6} in. per in. per hr, a rate which would produce a strain of 0.05 in. in a 5-ft length in 10 years. For turbine blades that in the high-temperature part are usually of small dimensions and are subjected to their maximum stress only on a small portion of their length, a much higher creep rate is permissible, say, 10^{-5} in. per in. per hr, and a similar figure may be taken as applicable to such items as valves, which in any case require readjustment from time to time. Valve stresses are, however, usually quite indeterminate, and design can be based only on experience.

Data on creep rates as low as 10^{-6} can be obtained only by very careful research extending over a considerable period of time. Though a great deal of information relating to creep has been accumulated, much of it applies to rates higher than 10^{-5}, and caution is necessary in drawing inferences from this, because materials showing good properties at the higher rates may not maintain their relative superiority at the lower rates. The good results obtained with steels containing from 0.5 to 1 per cent of molybdenum are leading to the employment of these alloys for an increasing number of uses, and they are now generally regarded as the most suitable materials for both castings and forgings that have to operate at temperatures above 800 F.

The development of these molybdenum alloys has had an important influence on the technique of steel production, and they have found many applications where high temperatures are not necessarily involved. It seems likely that in the future their use in turbine work will not be limited to cases involving temperatures above 800 F.

An additional and somewhat different problem arises in the case of bolts for the turbine and steam-pipe joints. It is due to the phenomenon of stress-temperature embrittlement. If, for instance, a nickel-steel bolt made from material with an Izod value of 50 ft-lb be subjected to stress at a temperature of 800 F for a few months and then tested, its Izod value will be found to have fallen to 3 or 4 ft-lb. This embrittlement may not perhaps be as serious as it sounds, especially as some uncertainty still seems to exist as to whether a corresponding change occurs in its ability to resist shock stresses at working temperature. The possibility of bolts in service being subjected at one time or another to shock stresses when either hot or cold cannot, however, be ignored. Such conditions might, for example, arise due to water hammer. In these circumstances embrittled bolts would certainly be a source of weakness.

The embrittlement effect seems to be chiefly associated with nickel alloys—it is characteristic of the nickel and nickel-chrome steels that in the past have been so widely used for bolts; but there appears to be some evidence that it can be prevented by the introduction of molybdenum. Opinion is divided as to whether molybdenum in a nickel alloy is effective in this respect. Some metallurgists have been led by their research to the conclusion that the embrittlement effect is inseparably connected with the use of nickel, and that alloys that do not contain nickel are much superior to those that do. The materials most favored at the present time for bolts for high-temperature service contain from $^1/_2$ to 1 per cent of molybdenum, about 1 per cent of chromium, nickel (if employed at all) about 2 per cent, and carbon varying from 0.3 to 0.5 per cent according to the tensile strength specified.

Reheating. A very substantial gain in the steam-cycle efficiency becomes available if intermediate resuperheating, generally called reheating, is adopted. So much attention has been paid to this subject in technical papers and so many theoretical data have been published that the potential advantages of reheating can hardly fail to be generally appreciated. Nevertheless, its merits have not up to the present received the recognition they would seem to deserve; at all events, they have not received the practical recognition of being generally adopted, even for large plants.

The new station now being erected at Dunston for the Newcastle-upon-Tyne Electric Supply Company is a notable exception in this respect and will be referred to more fully later.

While there would seem to be no doubt that reheating will become an essential part of the thermodynamic cycle in the future and is a logical corollary to the use of higher pressures, the progress of its development has been slow. The pioneer installations in this country have had to contend with many difficulties and adverse circumstances, some of them not directly connected with the reheating, and others easily corrected in the light of the experience gained. Consequently, operating results have not always appeared very convincing and have sometimes been misinterpreted by the skeptic.

The earliest reheating installations were put in by the Newcastle-upon-Tyne Electric Supply Company about 1918. In that year a reheater supplied with live steam at a pressure of 275 lb per sq in. was put into service on an 11,000-kw tandem turbine at Carville Power Station. In the following year at Blaydon Burn, a small waste-heat station operated by the same company, a separately fired reheater employing coke-oven gas was set to work and reheated the steam between the cylinders of a two-cylinder geared turbine to 400 F. Owing to the low temperature of the reheat the actual gain in economy in both these installations was small, but the experience gained with them paved the way to the adoption of flue-gas reheaters integral with the boiler in the North Tees "A" Station in 1920, and later in connection with a 40,000-kw unit at the Barking Station of the County of London Electric Supply Company. The latter was the first installation in which the reheating was carried right up to the initial temperature. The test results on these plants have demonstrated quite convincingly that the full theoretical reductions in turbine heat consumption are realized.

One of the objections to reheating frequently raised is the complication of the pipework to and from the reheater. Experience with existing installations has shown that the accommodation of the pipes and the necessary provision for their expansion is not really difficult. Operating results have proved that the problems peculiar to reheat—such, for example, as the regulation of the temperature and the provision of adequate emergency control—can be dealt with quite satisfactorily. Little or no difficulty has been experienced in the general operation of the plants.

It is of course essential that reheat units should operate as base-load machines and that they should run for long periods with a reasonably good load factor. Frequent starting and stopping involves the loss of much of the advantage of the reheat, owing to the time taken on each occasion to reach steady conditions. This consideration has perhaps had much to do with the tardy progress of reheat, for the ideal of base-load machines is apt to be elusive, and the adoption of reheating can be justified

on economic grounds only if the potential saving is realized.

So far as the turbine itself is concerned, continuous running presents no difficulty, but the boiler must be laid off for repairs to refractories or to grates. As with existing systems the turbine is tied in with its own reheater boiler, this involves either shutting down the turbine or running without reheating. In consequence, much importance attaches to the frequency of these boiler stoppages. For similar reasons it is essential that the condensing plant should operate for as long as possible without requiring tube cleaning, and the periods for boiler overhauls and condenser cleaning must correspond so that they can be carried out together. This condition may not be easy to attain, for it is equally important to maintain a reasonably good vacuum—a drop of 1 in. neutralizes half the gain due to the reheat. Much depends of course on the circulating-water conditions at the individual station. In cases where serious difficulty has been encountered from fouling of tubes due to the growth of algae, chlorination of the water has given very satisfactory results.

Reheating by means of live steam, which at one period became very much favored in the United States, has not received much support in England. The system is subject to the limitation that the gain, in comparison with the non-reheat system operating with the same total steam temperature, is inevitably small and insufficient to make it attractive. The view usually has been taken that, wherever there is a good case for reheating, boiler reheating up to the full temperature affords the sounder proposition.

So far as the author is aware, reheating by steam has been applied only to one recent machine. This is at the Valley Road Power Station of the Bradford Corporation. The turbine, a tandem unit of 30,000 kw, built by the English Electric Company, operates on a stop-valve pressure of 200 lb per sq in., but there is a boiler at a pressure of 1100 lb per sq in. supplying a high-pressure turbine which exhausts into the 200-lb steam range, and steam from the 1100-lb boiler is utilized for reheating.

Feed Heating. The maximum theoretical advantage that can be derived from feed heating by bled steam increases with the number of stages adopted; so also does the most economical value of the final feed temperature. For the stages beyond the fourth, however, the percentage is small, and practical conditions such as initial cost and additional complication usually limit the choice to this number. As in most installations an evaporator taking bled steam is incorporated, it is usual to supply the evaporator with steam from the same bleeding point on the turbine as one of the higher feed-heat stages, and to condense the evaporate in the next lower stage. The appropriate final temperature of the feed under these conditions is that corresponding to about 70 per cent of the saturation temperature at boiler pressure. As the feed temperature necessarily varies with the output, this value is normally designed for at economical load, so that the best conditions of feed heating may be maintained at maximum load and also for a reasonable range below economical load.

Feed heaters with an outlet temperature up to 220 F can generally be installed on the suction side of the feed pumps, which are arranged to suit this suction temperature. Above this temperature high-pressure heaters have to be employed on the discharge side of the feed pump and provided with an automatically controlled bypass, so that in the event of a tube failure the turbine is protected from flooding without the supply of feed to the boiler being interrupted.

The practice of draining each heater into the next lower stage and finally through a drain cooler to the condenser has the merit of avoiding the use of a small motor pump to return the condensed steam to the feed system at each stage, and is for this reason frequently preferred by operating engineers. The use of drain pumps does, however, give a slightly better economy. The difference may amount to more than half of 1 per cent, which is an important consideration on a large unit, but the greater part of this gain can be secured by utilizing a pump for the last stage only and draining the others in cascade.

A special deaeration plant is not generally found necessary, as it is possible, if the system is properly arranged, to keep the oxygen content sufficiently low by deaerating the make-up in the condenser. The high condensate temperature obtained with modern condensers helps to make them efficient deaerators.

Some Details of Design

Rotor Forgings. Of all the factors that influence the progress of turbine design, the most important is the production of sound steel. So much depends on the reliability of the forgings available that the turbine manufacturer finds himself compelled to take an active and leading part in the development of steel-works practice. The close cooperation of both interests has enabled rapid strides to be made in steel production during the last few years, and a remarkably high standard has been achieved in the forgings available today for large turbine and alternator rotors.

A rigorous control is exercised on the passage of the steel right through from the refining of the metal and the pouring to the final treatment of the rough-machined forging. All rotor and disk forgings used by the author's firm are manufactured in strict accordance with its own specification, which regulates the entire process so that the internal strains due to inequalities of temperature are kept down to an absolute minimum throughout. A new method of casting ingots, due to the late Sir Charles Parsons, was developed a year or two before his death. In this method the ingot is cast cylindrical and with a diameter about twice its height. The mold is constructed with a massive chill at the bottom so that the cooling proceeds from the bottom upward, the sides of the mold being made of firebrick preheated to 1000 C. Heat is applied to the top of the ingot to delay setting of the metal. This method, which is described more fully in a paper read before the Iron and Steel Institute (*Journal of Iron and Steel Institute*, 1929, Vol. 119, page 255), has proved extremely successful. The segregates instead of being forced in toward the center are driven up continuously as the ingot cools from the bottom, and are accumulated in the top layer, so that not only is the resulting steel much freer from harmful segregates and axial unsoundness, but also the discard is very much reduced.

All rotor forgings are of course bored, and where possible chambered, and are examined by means of a borescope. In addition, all exposed faces and journals are sulphur-printed as a check on segregates and ingot corner weakness. When all tests have been passed, the rotor is machined nearly to final dimensions, leaving only a small allowance for finishing, and then run up in a bombproof shelter to a speed of $1^1/_2$ times the working speed, corresponding to double stress. This test affords a final assurance that the material is perfectly sound and up to specification in every respect, although the precautions taken in its examination and physical tests make the chances of a failure on overspeed remote. Turbine disks are subjected individually to a similar overspeed test before mounting on the shaft, their dimensions being carefully gaged before and after the test.

Cylinder Construction. The design of high-pressure cylinders resolves itself mainly into a question of reducing to a minimum the strains and distortions which result from inequalities of temperature. With this end in view, a design has been adopted which aims at providing a rigid and symmetrical tubular core which will attain a sensibly uniform temperature across transverse sections, and will under all conditions dominate the shape of the structure. The steam inlets, feed-heating ports, and so forth are arranged as flexible belts which, where their natural expansion differs from that of the main core, can accommodate themselves without introducing appreciable constraints. Three views of

such a cylinder are shown in Fig. 1. It will be seen that the tubular core which carries the blading is made of very heavy-section metal. It is provided with a series of symmetrically disposed ports at each belt for the admission of steam. The walls of the belts themselves are made no thicker than is necessary to sustain the pressure and are shaped so as to give flexibility. The flanges are very deep and the bolts are kept close in, also the outer portion of the flange is parted at each bolt hole; thus the same effective thickness of metal is maintained all around, and stresses due to pull of the cooler part of the flange are avoided. The joint is strengthened by the provision of long studs through bosses in the cover close up to the inner core, these bosses being fitted with mild-steel liners in cases where the complexity of the casting makes this desirable.

When the steel portion of the cylinder is made in two sections with a transverse joint between them, this joint is held by heavy countersunk rivets and is welded all around on the inside. Rivets have the advantage that they can be pitched closer than bolts,

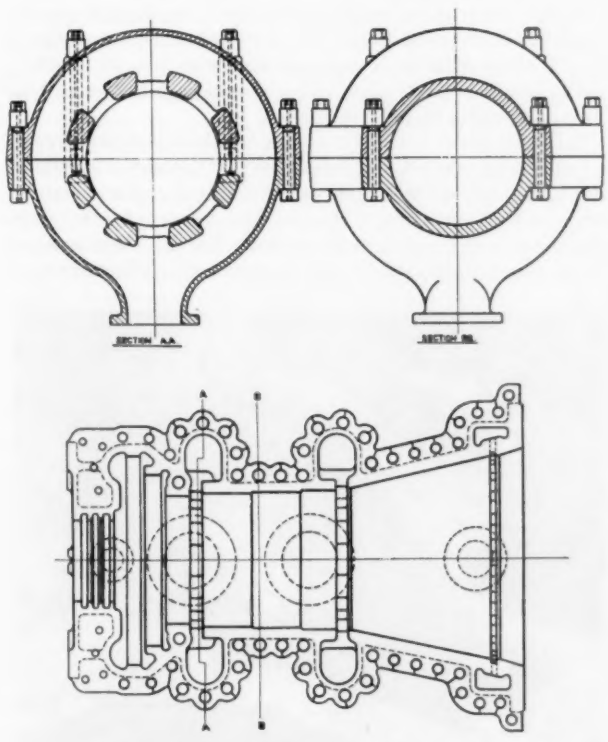

FIG. 1 ARRANGEMENT OF STEAM-INLET BELTS

and also as there are no projecting heads the bolts in the horizontal joint can be brought up closer to the vertical flange.

Steel cylinder castings are fully annealed at the foundry. After removing the headers, they are dressed and cleaned and then charged into an annealing furnace, brought up to 920 C, and afterward cooled down gradually in the furnace to atmospheric temperature. After machining and boring to $^1/_{16}$ in. off finished size, they are mounted on end on a bogey and put into a totally enclosed furnace, where they are brought up to 500 C, and again cooled down very slowly. This second treatment removes any internal stresses that may remain after the machining and that otherwise might be slowly released in service.

The practice of heating the cylinder-joint bolts to tighten them up has the advantage that clearance for a heavy spanner is no longer required—the bolts can be pitched closer together and they also can be tightened to an equal and determinate stress. The arrangement of electric heating shown in Fig. 2 has proved to be simple, speedy, and effective. It is important that the bolts should be heated up as rapidly as possible; otherwise too much heat will be conducted to the flange. For this reason a carbon rod that will absorb about 4 kw is much superior as the heating medium to any form of wire-wound element. Tightening of, say, a 4-in. bolt will take only from 15 to 20 min.

The electric heating is used for both closing in and for opening out the turbine, and since there is no pressure on the thread when

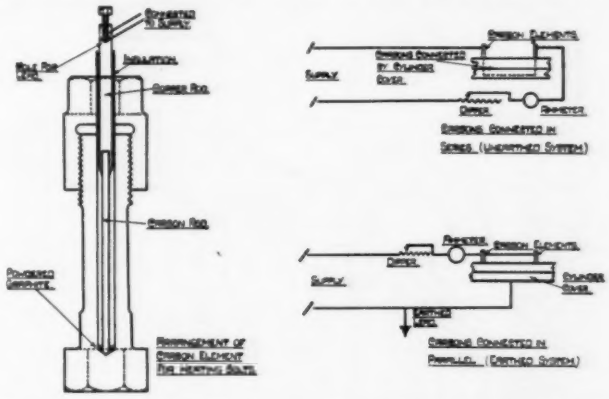

FIG. 2 ELECTRICAL METHOD OF TIGHTENING CYLINDER BOLTS

the nut is turned, it has been found very useful in reducing the seizing of nuts, which used to cause so much trouble when machines were being opened out after prolonged running on high-temperature steam. As a further precaution against seizing, it has been found advantageous to spray the threads of all bolts with aluminum. The aluminum appears to protect the surface of the steel from oxidation, and though an oxide film probably forms on the aluminum, this can be sheared comparatively easily when it is desired to slacken the bolt.

As an alternative to the electric method, gas heating is sometimes employed, but it is open to the objection that it is not possible to heat the bolt rapidly and uniformly over its whole length by gas. Furthermore, gas is not available in many power stations, and if portable cylinders of compressed gas have to be employed, the method becomes relatively costly.

Blade Materials. Blade corrosion, a few years ago one of the most frequent causes of turbine troubles, is no longer a source of anxiety to the operating engineer. This is due primarily to the development of the so-called stainless steels. The refinements introduced into the feedwater equipment of the power station of today have set a high standard for the purity of the feed, and it is seldom that a case is met with where the steam contains any appreciable quantity of impurities likely to cause serious corrosion of modern materials. For general purposes, the most useful grade of stainless steel is that known in the steel trade as stainless iron. It contains about 13 per cent of chromium and has a carbon content of 0.1 per cent. Stainless iron is to be preferred to the higher carbon stainless steels because it is freer from the danger of becoming brittle due to air hardening during manufacture. Its mechanical properties are such that it is suitable for the higher-stressed low-pressure blading, at least up to tip speeds of 1050 fps, and it gives equally good results at the high-temperature end of the turbine. For brazing, chromium steels require treatment different from carbon steel, chiefly because the chromium oxide requires a longer time for fluxing. Some difficulty was experienced when it was first used due to the failure of manganese-copper shrouds which began to disintegrate in service and were found to have been permanently affected by the high brazing temperature. The difficulty was eliminated by employ-

ing monel metal instead of manganese copper for the shroud material.

Stainless iron is not suitable in cases where salt is present in the steam, as it is not highly resistive to chlorides. Occasionally in industrial plants it is not possible at all times to keep the concentration of salt in the boilers low enough to prevent some chloride being carried over by the steam. In such cases the only satisfactory solution appears to be the use of more costly materials for the blading. Either austenitic steels or non-ferrous alloys such as monel metal may be used. It is, however, essential to

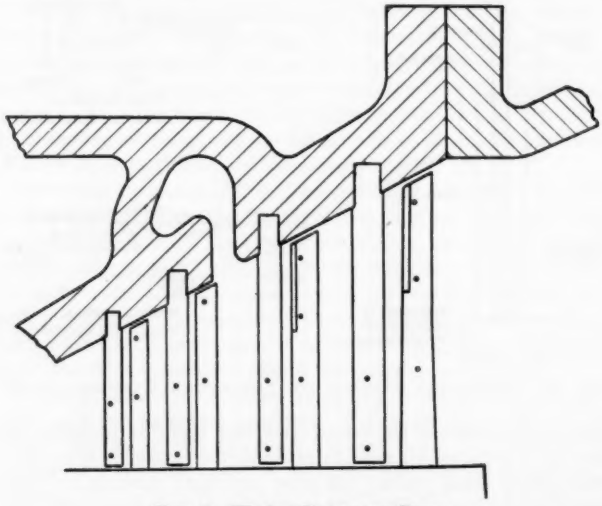

FIG. 3 WATER-DRAINAGE BELT

take all possible steps to avoid the presence of chlorides, as even if a resistive material is employed for the blading, the problem of corrosion of other parts, such as valve spindles, gland journals, and cylinder bores, still remains.

Erosion. Just as the difficulty of corrosion was being successfully mastered, a new and unforeseen blading problem began to present itself. As advances were made in peripheral speeds, a stage was reached at which the erosion of the exhaust-end blades by the impact of the water of condensation became rapid enough to suggest that it might prove to be the most serious factor limiting further progress.

Much confusion has resulted in the past from a failure to distinguish the difference between erosion and corrosion. Properly applied, the term "erosion" means wastage by a purely mechanical action—that is, by the disintegration of the surface layer of the blade into minute particles, without any chemical change whatever.

It is convenient to divide the methods employed to prevent erosion into two classes, according to whether they aim at the production of blades capable of resisting the action of the water or whether they depend on reducing the quantity of water striking the blades by withdrawing it from the turbine as it condenses. To meet the severe conditions obtaining at the present day in high-speed turbines, it is desirable to make use of both of these methods. By this means the longest life for very high-speed blades can be obtained. Were it possible to eliminate the water entirely, this would of course remove the cause of the erosion, and would therefore be the most direct solution. Unfortunately, however, there are fundamental reasons why the water cannot be entirely eliminated. Properly arranged, a simple system of drainage can be made to remove an appreciable quantity, but it does not appear to be possible even with the most elaborate arrangement to get rid of anything approaching the whole of the water.

It is reasonable to assume that the water that causes erosion of the last row is limited to that which condenses out and forms drops on the blades of the preceding guide row. The water condensed in the earlier stages will have been thrown out to the bore of the casing by centrifugal force and will for the most part be retained there, passing through to the exhaust as a layer on the cylinder. A small proportion of this water at the top will tend to leave the casing, as the effect of gravity is not quite negligible. This is probably responsible for the rounding off of the blade tips frequently observed.

A form of drainage belt arranged to trap as much as possible of the water accumulated on the casing is shown diagrammatically in Fig. 3. This belt is connected to a small feed heater, through which a portion of the condensate is passed in parallel with the ejector condensers. This facilitates withdrawal of the water by creating an appreciable outward flow of steam through the port. It also will be noted that the tips of the rotor blades in the preceding row fractionally overlap the metal of the casing. The layer of water flowing from the casing bore into the mouth of the belt acts as a seal to prevent steam leakage.

With a view to producing blades with the highest possible degree of resistance to erosion, the firm with which the author is associated has carried out extensive researches into the problem, and as this has led to some rather striking conclusions, a brief description will perhaps be of interest.

Test equipment was constructed in which the conditions of an actual turbine exhaust were reproduced. It consisted essentially of a bladed spindle that could be rotated in a casing containing steam at high vacuum and charged with a spray of water drops which traversed the path of the blades. The drive was arranged so that speeds up to 1100 fps could be obtained. The water spray

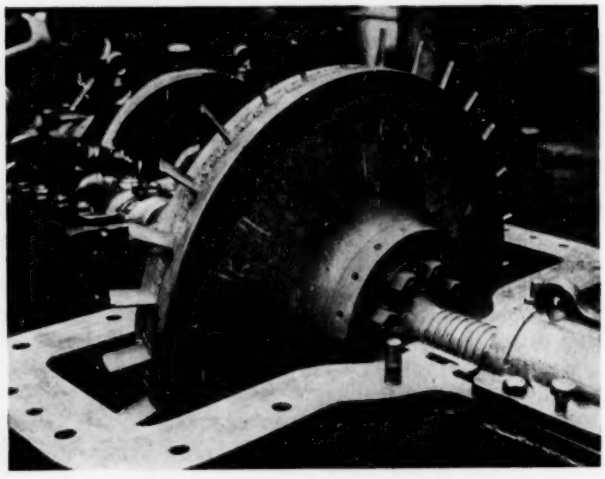

FIG. 4 EROSION-TEST EQUIPMENT

was produced by two oil-fuel burner nozzles that discharged the water in the form of a spinning cone of finely divided particles. The spray was arranged for the correct drop size and gave as fair a representation of turbine conditions as is obtainable, but the actual quantity of water producing erosion was increased so as greatly to accelerate the action.

A photograph of the apparatus showing the bladed rotor is reproduced in Fig. 4.

At the outset it was realized that, in general, the harder the material the higher would be its resistance to disintegration by a purely mechanical action, but it was not known definitely whether other factors might enter into the question that would make some materials more suitable than others by virtue of properties not directly related to hardness. The investigation showed con-

clusively that hardness is the essential property which determines the resistance to erosion by water impact. This property is most conveniently measured by a Brinell or equivalent test, and the comparative resistance of different materials may be predicted directly from their Brinell numbers.

It appears logical to suppose that ductility would influence the rate of disintegration by erosion as between two materials of equal hardness. This, however, can only be inferred and has no direct practical application, because among materials of the class, which by virtue of their extreme hardness are most effectively employed to resist erosion at high impact speeds, it is not possible to obtain any appreciable ductility.

In commercial practice the greatest degree of hardness can be obtained with the high-speed tool steels appropriately treated, and these have been shown to possess the highest resistance and have been found to be the most suitable for blade protection.

Another important fact that had not previously been appreciated was brought out by these experiments—namely, that water impact will cause erosion even though the yield point of the material is far above the calculated value of the resulting fluid pressure. The most satisfactory explanation for this is afforded by the supposition that the pressure is generated, not on a smooth surface, but at the bottom of a small pit in the metal. In this case tensile stress much greater than the pressure itself would be possible across the fibers surrounding the apex of the cavity. As a consequence of this, though theoretical considerations enable an expression to be found connecting the fluid pressure with the velocity of impact, no similar relation exists between the velocity and the stress produced in the metal. It is therefore not possible to deduce any useful relation between the yield point of a material and its resistances or to obtain experimental confirmation of the calculated value of the pressure. For the same reason it is not possible to find for any material a limiting or critical value for the impact velocity below which erosion cannot occur.

A typical example of the form of blade now used is shown in Fig. 5 to illustrate the manner in which the protection against erosion is applied. The particular example figured is employed for the last row in 3000-rpm machines with tip speeds in the neighborhood of 1000 fps. The blade itself is rolled integral with the root and is tapered in section from the root to a point halfway up the blade. From this point to the tip the profile is parallel and has the section shown in the figure. The ratio of the cross-sectional area at the root to that of the parallel upper portion is 3 to 1, a value which permits of an efficient design of blade and at the same time keeps the centrifugal stresses moderate. The blade profile is twisted so as to give the appropriate outlet angle at each individual point in its length. An independent erosion-resisting shield is attached to the upper portion of the inlet edge and on the convex side. As the blade and shield are separate, each can be made in the material best adapted for its purpose. The properties required in materials suitable for blades differ fundamentally from those required to resist erosion. A blade material must, for example, possess adequate ductility to preclude the possibility of failure from fatigue under the influence of any vibration stresses to which it may be subjected in operation. It also must be suitable in every way for the processes of blade manufacture. On the other hand, the essential property for resisting erosion is hardness, a property possessed in the greatest degree by materials of a class quite unsuited for making into blades, but which can quite conveniently be employed for shields.

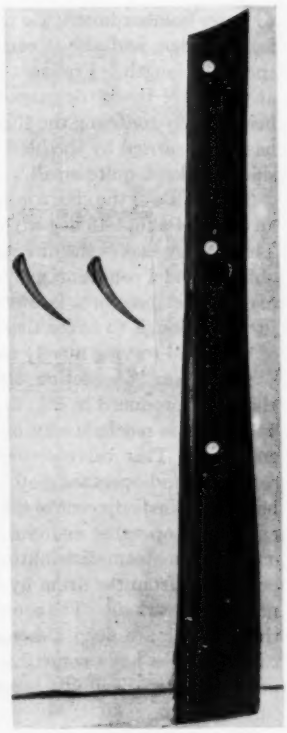

Fig. 5 Protected Rotor Blade

Another feature of the separate shield is the ease with which it can be removed and renewed. If in process of time the shields are worn down and replacement becomes necessary, the operation of renewing them is a very small matter in comparison with the alternative of replacing the complete row of blades. As the shield need be applied only over that area of the blade which is subjected

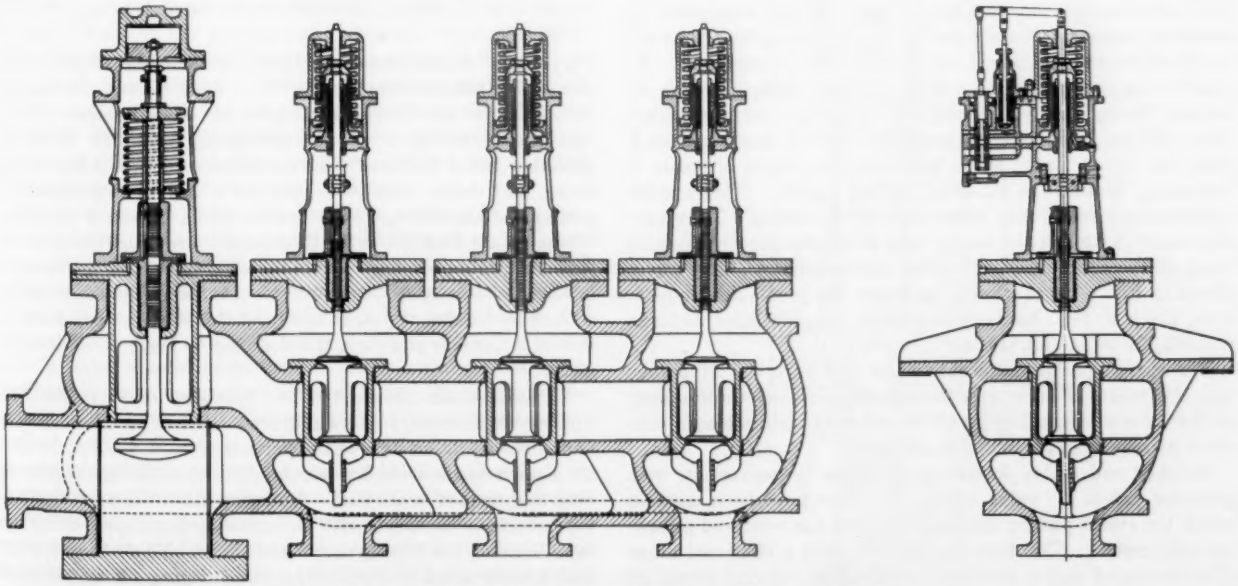

Fig. 6 High-Pressure Steam Chest and Governor Relay

to water bombardment, the protection can be concentrated on the leading edge, and also it can be confined to a limited portion of the blade length. Frequently the erosion is confined to a region at the tip of the blade extending for, say, one-third of the blade height. By confining the shield to this area, the extra load which has to be carried by the blade, due to the centrifugal force of the shield, is kept quite small.

The profile of the shield is beveled so as to have a flat face set at an angle of about 45 deg with the plane of rotation of the blades. This feature makes the direction of impact of the water and blade oblique, and a condition much less favorable to the building up of high impact pressures is therefore obtained. The bevel extends just far enough to cover the whole of the exposed area, the tail of the shield serving merely to blend it into the blade profile.

Valve Gear. A section through a large high-pressure steam chest is reproduced in Fig. 6. The first valve is the emergency valve and is mechanically operated from a centrifugal runaway governor. This valve serves as an emergency control only, a separate hand-operated stop valve for use in starting up the plant being provided adjacent to the steam chest. In addition, a motor-operated stop valve manipulated from the control room is fitted on the main steam-distributing drum. The turbine can therefore be isolated from the drum by two positively closing valves during periods of overhaul. The connections between the steam chest and the cylinder are deep U-bends of corrugated pipe. These corrugated pipes have come into very general use for a variety of purposes where flexibility is required, both in the boiler house and turbine room.

There are three governor valves, all of equal size, fed from the common central port of the chest and controlling the steam for 60, 80, and 100 per cent load, respectively. The emergency valve and the governor valves are all forged in one piece with their spindles. This makes them very robust and avoids the use of nuts or other fixings, exposed to the full temperature of the steam, which are likely to be a source of weakness. The spindle glands are plain bushes of pearlitic iron, with a fine clearance and provided with two leak-off ports for the leakage steam. Pearlitic iron has proved most successful for this purpose and gives no trouble through distortion, even on the highest temperature machines.

The design of the governor valves is a matter of some importance. The momentum of the steam passing through the valve at high velocity is very large, particularly where the steam pressure, and consequently the density, is high. If this momentum is altered by contact with some part of the valve away from the seat, considerable out-of-balance forces on the valve are produced. As these forces depend on the weight of steam passing and on its velocity through the valve seat, their magnitude varies considerably with the load, being in general greatest at about half-load. They fall off at higher loads, although the weight of steam is increasing, because the velocity is falling rapidly. These rather indeterminate forces may cause unstable governing. They may also cause chatter of the valves, and as a consequence excessive wear, and sometimes actual fracture of the spindles. The valves shown in Fig. 6 are of what is known as the profile double-plate type, and their form has been evolved so as to eliminate, as far as possible, forces of this nature.

The curved profiles adjacent to the seat have the advantage that the ratio of effective area to valve lift increases continuously as the valve opens, a feature which assists in maintaining a constant sensitivity of governing at all loads.

Another and rather interesting problem in connection with governor valves is "valve whistle." There have been cases in which the steam passing through the valve has produced a high-pitched screech. This has occurred only over a restricted range of valve travel and is produced by the high-velocity steam jet from the valve impinging on the edge of some part of the seating or chest. Although it has proved difficult to locate the exact point where the screech was produced, it has been effectively silenced by an alteration to the valve profile.

The arrangement of the governor relay is shown in Fig. 6. The small auxiliary piston shown between the power piston and its control plunger is operated by an independent oil system, the pressure in which is controlled by the speed governor. The regulation of the pressure in this auxiliary system is effected directly by the movement of the governor sleeve, so that the connection between the governor and the power relay is by an oil link and not by a lever train.

In the case of reheat units, control of the steam stored in the reheater is effected by the provision of valve chests at the inlet to the low-pressure turbine. The valves are controlled by a centrifugal governor independent of the main governor, and are arranged to be normally full open, but to respond very quickly to the governor if the turbine speed reaches 5 per cent above normal. This avoids the danger of the machine tripping out on overspeed due to the reheater capacity.

Turning Gear. The practice of providing large machines with motor-driven turning gears is now becoming general. The necessity for such a fitting arises from the fact that the cooling of a stationary machine after shutting down does not proceed evenly. As the heat stored in the hot end of the spindle gradually soaks through into the colder end, the average temperature of the

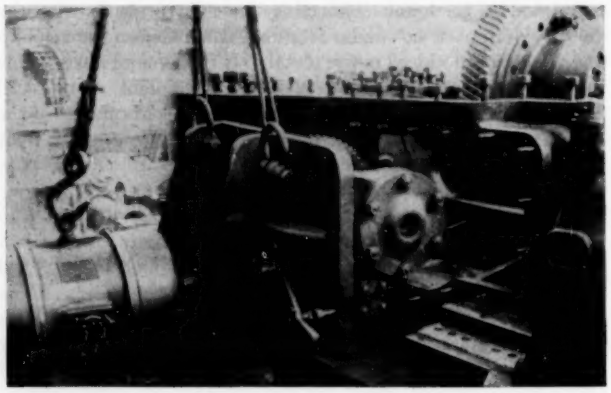

FIG. 7 TURNING-GEAR ASSEMBLY

top portion tends to rise above that of the bottom portion. The greater the temperature gradient initially and the more massive the shaft, the more pronounced does this effect become. Large shafts may thereby be bowed sufficiently to throw them appreciably out of balance. The distortion may persist for several hours, and during this period difficulty may be experienced in getting the machine up to speed without objectionable vibration. Owing to the time taken for the temperature distribution to adjust itself, vibration may persist for some time after the machine has been put on load. To avoid this it is necessary to control the cooling by turning the shaft slowly; if this is done a symmetrical flow of heat takes place and the shaft has no longer a tendency to distort.

To achieve this result it is not necessary to keep the shaft turning continuously; it is sufficient to turn it at intervals, perhaps once an hour, through a portion of a revolution, so that the same influences which produce a distortion during one interval tend to correct it in another. A turning gear of this intermittent type should be arranged with an extremely large speed-reduction ratio between the driving motor and the turbine shaft, as a dead-slow turbine speed is of advantage in producing a large torque to overcome the initial friction. If, however, the turning gear is of

the continuous type, the speed of the journals must be high enough to maintain the oil film in the bearings; i.e., it must be of the order of 1 fps, corresponding to, say, 15 rpm rolling speed for an average 1500-rpm machine. As the motor speed in this case would normally be 1500 rpm, the gear ratio is limited to about 100 to 1. To obtain a starting torque capable of overcoming the friction of a dry bearing, an unduly large motor would be required. It therefore becomes necessary to provide a high-pressure oil system connected to the bearings, which can be used to lift the journal off the bearing and to establish an oil film before the turning-gear motor is switched in. Oil pressures of 1000 to 1200 lb per sq in. are usual for this purpose, supplied from a small motor-driven, multi-throw plunger pump.

Apart from the turning of the shaft during a temporary shutdown, the turning gear has another application, of particular importance for machines operating with very high-temperature steam, and that is to simplify the process of starting up from cold. For this purpose the turning gear must be of the continuous type, which on this account is to be preferred to the intermittent type. It is essential when starting a cold machine to have the spindle rotating during the warming-up period; otherwise unequal heating of the spindle is almost unavoidable. If it is started from rest by steam, a very large amount of hot steam has to be passed suddenly into the turbine, and this involves subjecting the cold cylinder and valve chests to severe temperature shocks. If, however, the turning gear is utilized to rotate the spindle, only enough steam need be admitted to warm the plant up gradually and uniformly. In this case the procedure is, first, to raise some vacuum, say about 10 in., then to engage and start the turning gear and open the stop-valve bypass a small amount. As the vacuum rises, a point will probably be reached where the warming-up steam is sufficient to keep the spindle rolling. The turning gear will then automatically disengage, and the motor can be switched off. When the vacuum has reached, say, 25 in., running up to speed is commenced.

The location of the turning gear on the turbine depends on the arrangement of the machine. On single-cylinder units or tandems with double-flow low-pressure cylinders, the motor and gear have usually to be accommodated between the cheeks of the exhaust, and the drive is transmitted to the turbine shaft through a toothed wheel attached to the coupling. A very neat arrangement can be obtained when the unit includes a single-flow intermediate-pressure or low-pressure turbine, by fitting the gear below the main shaft in the intermediate pedestal, the motor being supported on a bracket at floor level, as shown in Fig. 7. In the example illustrated, the first reduction is a worm gear, but a helical gear is used for the second reduction, as it has the advantage of being independent of the axial adjustment of the spindle. The pinion slides on a long-pitched screw thread, and engagement is effected by a hand lever.

Shaft Alignment. There has been much variation in the practice of different makers with regard to the type of coupling employed between turbine and alternator rotors. The use of a solid flanged coupling is attractive, because it leads to a simplification, not only in the coupling itself, but also in the thrust blocks, and thereby effects some saving in length. There is today a movement in favor of solid couplings, but there is some hesitation in introducing them generally. While many installations are operating excellently with solid couplings, there have been others in which the experience has not been so satisfactory and where it has proved necessary to revert to couplings of the flexible type. There seems to be no reason to doubt their suitability provided the balance of the individual rotors is good and the alignment accurate. Such conditions should not be difficult to obtain—for example, between a low-pressure turbine and its alternator rotor; and here, therefore, the application of a solid coupling seems

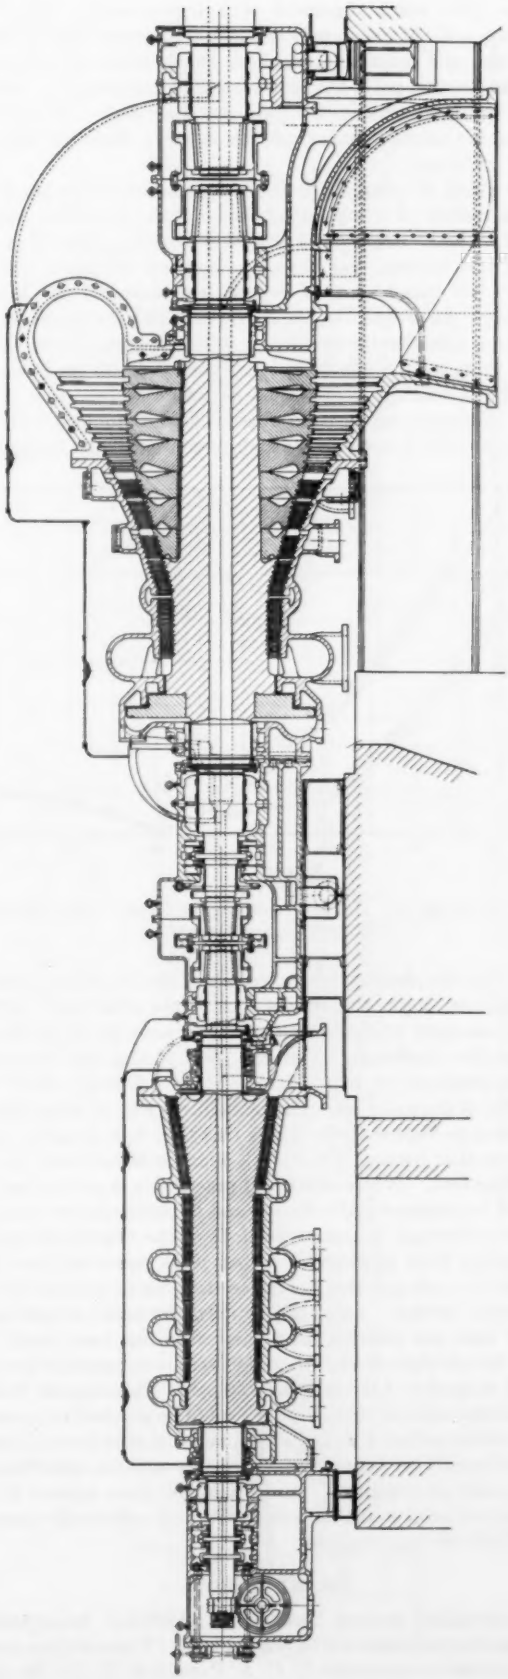

Fig. 8 50,000-Kw Tandem-Cylinder Turbine, 1500 Rpm (Parsons)

logical. The exact alignment of a high-pressure cylinder is, however, not always so easy to achieve, because the supports, pedestals, and concrete foundation blocks alike are subject to considerable changes of temperature due to the proximity of steam pipes, and their expansion affects the alignment. To meet the varying conditions arising from this cause, a flexible coupling is to be preferred.

The effects of unequal heating of foundation blocks are nowadays a matter of some importance. Many machines are arranged with the steam chest and its connecting pipes all on one side of the turbine, and the pipes between the chest and the cylinder are usually carried several feet down for the sake of flexibility. Consequently, the concrete block gets heated on this side for a considerable proportion of its height. With a high steam temperature this may have the effect of producing an appreciable differential expansion between the two sides of the block. Instances can be cited where vibration troubles have been experienced due directly to the high-pressure cylinder being lifted

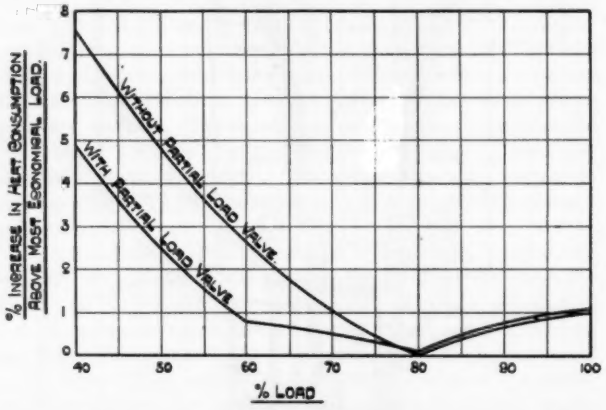

FIG. 9 CURVES OF HEAT CONSUMPTION WITH AND WITHOUT PARTIAL-LOAD VALVE

clear of the sole plate on the cooler side of the foundation, and so being left free to pivot about the foot on the other side. It has become necessary to take this factor into account in the design of foundation blocks and to arrange them so that such temperature gradients as are unavoidable do not adversely affect the alignment of the machine. The most direct way of doing this is of course so to dispose the hot parts that they do not radiate heat directly to that portion of the block which is immediately under the turbine foot. Where this is not practicable, a screen may be provided to intercept the radiation and to distribute the heat by conduction through the cooler portions of the foundation block. The simplest form of screen is a steel plate separated from the concrete by an air gap over the hot section, but in contact with it over the cool section. Cases have come under notice where harsh running that has resulted from this cause has been cured by setting the sole plate down on one side so as to compensate for the unequal expansion of the foundation block. This suggests that a very rational solution of the problem could be attained by mounting the steam end on a pad of elastic material which would compress sufficiently to maintain a reasonably uniform distribution of load under all conditions. Unfortunately, there appears to be no elastic material available with a structure sufficiently permanent to fulfil the requirements.

RECENT DESIGNS

A longitudinal section through a 50,000-kw two-cylinder 1500-rpm reaction turbine is shown in Fig. 8. Three of these units are now under construction by C. A. Parsons & Co. for the new station that is being erected at Dunston in connection with the conversion of the northeastern section of England to 50-cycle supply. The turbines are designed for 600 lb stop-valve pressure, 800 F temperature, and 29 in. vacuum, with intermediate reheating up to the initial temperature, and feed heating by bled steam to 350 F. The most economical point is at 40,000 kw load, or 80 per cent of the maximum continuous rating. With the operating conditions obtaining in England, this ratio of economical to maximum load seems to give the best overall results and has long been a standard that has not been departed from. The practice of building machines with large overload capacity has never been introduced in this country, though in point of fact by the use of partial-load valves the consumption at, say, 60 per cent can be brought down so near to the 80 per cent figure that a generally similar consumption characteristic is obtained down to this point.

The form of the heat-consumption curve for a machine with a partial-load valve is shown in Fig. 9, compared to that of a similar unit without the valve. This curve assumes that the condenser is designed for the 80 per cent load and that the circulating-water quantity is kept constant, so that the vacuum varies with the load. A rather curious condition arises in this connection in the case of a reheat machine, in that the steam consumption at 60 per cent load is actually lower than that at the most economical one, though the heat consumption is a little higher. This is of course due to the fact that at the lighter load more heat units are put in per pound of steam in the reheater.

The two-cylinder design with a single-flow low-pressure turbine enables the reheating to be arranged between the cylinders. This is a material advantage, because for this output at 1500 rpm the provision of reheating steam belts on the high-pressure turbine presents difficulties, and would involve some sacrifice of efficiency in this turbine. The tip speed at the exhaust end of the low-pressure turbine is very moderate, and ample exhaust area is obtained with both shaft and disks of such dimensions that very simple forgings can be employed for their manufacture.

The reheat pressure in this case is 115 lb per sq in. The glands of the high-pressure turbine are composite, a labyrinth being provided to break down the pressure, followed by a carbon-ring gland for sealing. The port between the two is connected to the low-pressure feed-heat belt. Water-sealed glands, so general in America, have never achieved the same measure of popularity in England for high-pressure turbines. This affords an interesting instance of divergence of practice in the two countries. Properly designed steam-sealed glands are undoubtedly remarkably free from mechanical troubles, but so long as they were provided with vent pipes they were apt to use them to excess This weakness has now been eliminated by the introduction of small condensers in place of the vent pipes. These may be of a very simple type, usually consisting of a coil of copper tube arranged to pass a small quantity of condensate from the extraction pump. The "visible discharge" from the gland is retained by allowing the condensed steam to drip into an open funnel.

In Fig. 10 is shown a three-cylinder turbine at 1500 rpm designed for conditions similar to the machines just described. This arrangement would be adapted for outputs of 75,000 to 100,000 kw. The steam is reheated between the h-p and i-p cylinders and is comparatively cool when it enters the double-flow low-pressure turbine, at which point the pressure is slightly below atmospheric.

Fig. 11 shows a section through a 75,000-kw three-cylinder tandem unit at 1500 rpm, by the British Thomson-Houston Company, at Rugby. Two of these units are being supplied for the new Barking Power Station of the County of London Electric Supply Company. The turbines are designed for a steam pressure of 600 lb per sq in. at the stop valve and a tem-

perature of 800 F and vacuum of 29 in. The most economical load is 60,000 kw, and at this load the feed is heated to 340 F by steam tapped from the turbine at four places.

The high-pressure cylinder contains a Curtis wheel and 19 single-row wheels of 36 in. mean diameter. The two-row stage is used for partial loads and is bypassed at the most economical. For maximum load, 10 of the single-row stages are bypassed. The intermediate-pressure cylinder has 20 stages, and from its exhaust the steam is conveyed through overhead interconnecting pipes to the double-flow low-pressure cylinder. This cylinder has only four stages at each end, with a mean diameter of 116 in. at the last row. Flexible couplings are used, and each rotor is located axially by its own thrust block. In the case of these units the glands in all three cylinders are of water-seal type.

A two-cylinder tandem turbine by the Metropolitan Vickers Company for the Clarence Dock Power Station of the Liverpool Corporation is shown in Fig. 12. This unit is designed for an economical load of 41,250 kw, with a continuous maximum rating of 51,250 kw, and runs at 1500 rpm. The steam conditions are 400 lb per sq in. stop-valve pressure, 800 F temperature, and 29 in. vacuum, but the full output can be obtained with 340 lb per sq in. stop-valve pressure and 675 F temperature. Steam for feed heating is supplied from three points on the l-p turbine, and an additional tapping is taken from the h-p turbine exhaust.

The high-pressure cylinder has 25 stages ranging from 42 in. to 53 in. mean diameter. On overload the first five stages are bypassed, and provision is made to bypass a further group of five stages to enable the output to be obtained on the lower steam pressure. In the low-pressure cylinder there are 17 stages with mean diameters rising from 60 in. at the inlet to 96 in. at the exhaust. The final stage is of the Baumann multi-exhaust type. A built-up construction is employed for the high-pressure diaphragms, the nozzle blades being individually machined and riveted to steel centers. The diaphragms of the low-pressure cylinder are of cast iron with cast-in steel blades.

A Bibby flexible coupling is used to connect the high-pressure and low-pressure turbine rotors, while the generator coupling is of the semi-flexible type, and consists of a corrugated-steel sleeve. Each turbine rotor is provided with a Michell thrust block.

The glands of the high-pressure turbine are of the labyrinth type with radial contacts. These glands, a detailed view of which is given in Fig. 13, are formed of steel segment rings. Both the stationary rings and the housings in which they are carried are supported by flat springs, the arrangement being intended to permit of displacement of either individual rings or the entire group without damage to the labyrinths, in the event of accidental contact occurring. This same type of gland is fitted at the inlet end of the low-pressure turbine, but the exhaust end has a water-sealed gland.

A recent 3000-rpm Parsons turbine is shown in Fig. 14. This is a tandem machine with an output of 30,000 kw. The double-flow low-pressure cylinder has a mean diameter of 60 in. at the last row. Fig. 15 illustrates a three-exhaust design, with the

same blade annulus at the exhaust, to give an output of 50,000 kw at 3000 rpm. This is a three-cylinder turbine arranged for reheating.

The English Electric Company has built a number of three-cylinder tandem machines at 3000 rpm, one of which is illustrated in Fig. 16. This is a 30,000-kw unit designed for a stop-valve pressure of 200 lb per sq in., 700 F temperature, and 28.5 in. vacuum, with feed heating to 227 F.

The high-pressure turbine is of the impulse type, with twelve stages of 36 in. mean diameter. The low-pressure consists of two single-flow cylinders with reaction blading arranged to exhaust into the condenser through a common opening. The mean diameter of the last row is 60 in. The interconnecting pipes between the high-pressure turbine and the first low-pressure cylinder are carried overhead, while the longer pipes to the second low-pressure cylinder are arranged below the floor.

A disk construction is employed for the two low-pressure rotors, and they are connected by a rigid coupling, on either side of which a journal bearing is provided, and also a pivoted pad thrust housed in the bearing shell. The thrust collars are formed on the coupling flanges. As the rotors are opposed, their end thrusts balance and no dummies are required. Semi-flexible couplings of the toothed-ring type are used for the high-pressure turbine and for the generator. Carbon rings are used for all the glands with the exception of the inlet end of the high-pressure cylinder, where a labyrinth is fitted.

In the built-up diaphragms developed by the English Electric Company and used for the high-pressure stages, the nozzle blades are milled in steel blocks, which are shaped so as to form, when assembled, the outer ring of the diaphragm. Countersunk screws are used to unite the outer portions of the blocks. The inner portions have a tenon which is riveted in a groove in the steel diaphragm center, steam tightness being insured by a vee-weld on the discharge side. A detail of the construction of these diaphragms is given in Fig. 17.

A 60-cycle Parsons machine, a 15,000-kw unit at 3600 rpm, is arranged with a duplex exhaust, a construction that has been very successfully used in a number of cases to obtain a large output from a single-cylinder plant, particularly where a short overall length is essential. The steam is divided at a pressure of about 4 lb per sq in. abs, and a single duct of large capacity in the top half of the machine is employed to carry the steam over to the second set of low-pressure blading, the corresponding space in the bottom half forming the exhaust from the first set. (See Fig. 18.)

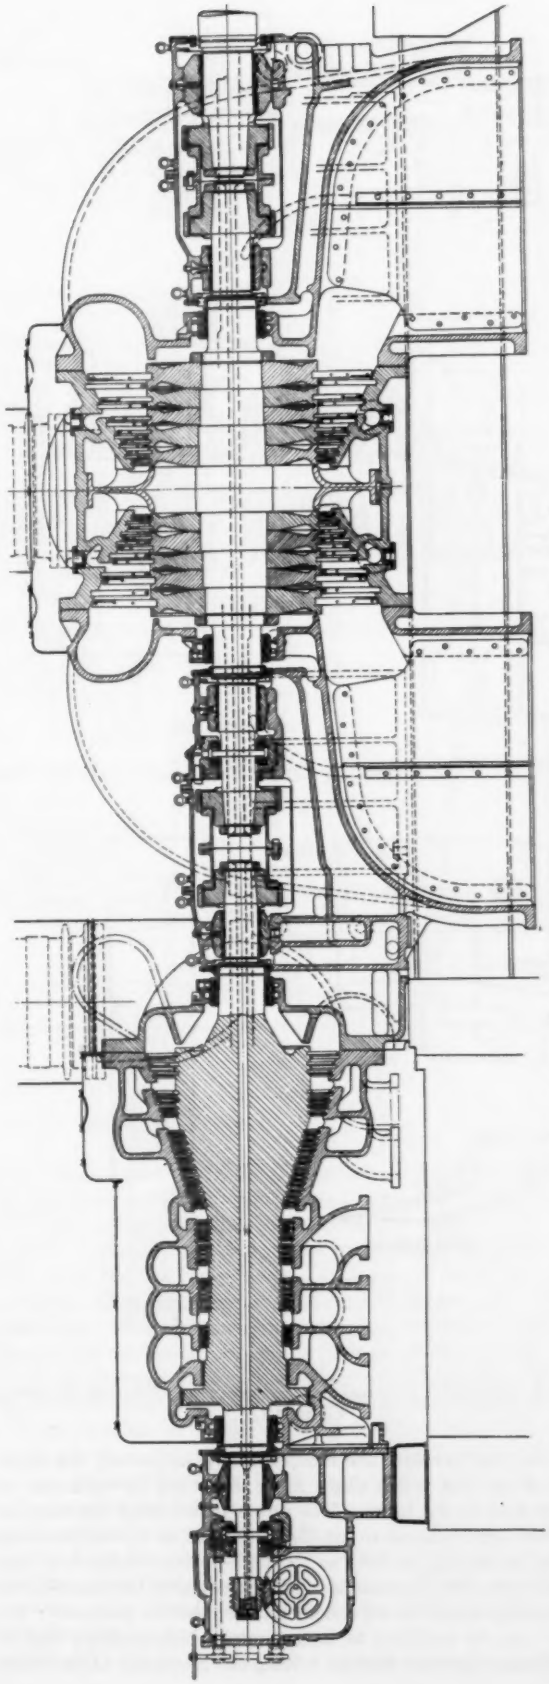

FIG. 14 30,000-KW TANDEM-CYLINDER TURBINE, 3000 RPM (PARSONS)

SOME TENDENCIES OF DEVELOPMENT

Double-Deck Compound Units. Cases sometimes arise in which the floor space occupied by a generating unit is a matter of extreme importance, and in which it is essential to adopt the type of unit which effects the greatest economy in this respect. Hitherto it has been possible in England to meet this requirement very effectively by the use of 3000 rpm, single-cylinder turbines with duplex exhausts. As the size of machines increases, however, it becomes necessary to consider compound units with one section disposed above the other, an arrangement that has already been adopted for a number of units in the United States.

A design of this type recently developed by the Parsons Company is shown in Fig. 19. The distinctive feature is that the high-pressure line is placed beneath the low-pressure line. There is ample space under the low-pressure turbine in which to dismantle the high-pressure turbine or, if required, to remove it complete, as the former is supported quite independently of the latter. Both turbines are thus readily accessible and the covers can be lifted without breaking the high-pressure steam-pipe joints.

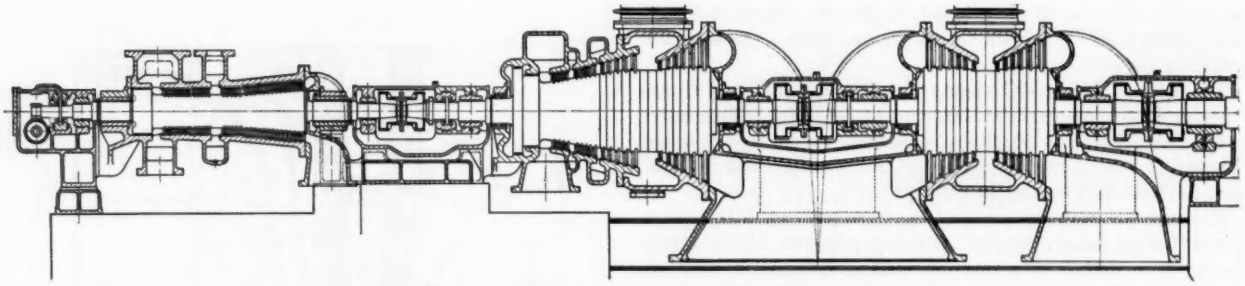

FIG. 15 50,000-KW THREE-CYLINDER TURBINE, 3000 RPM (PARSONS)

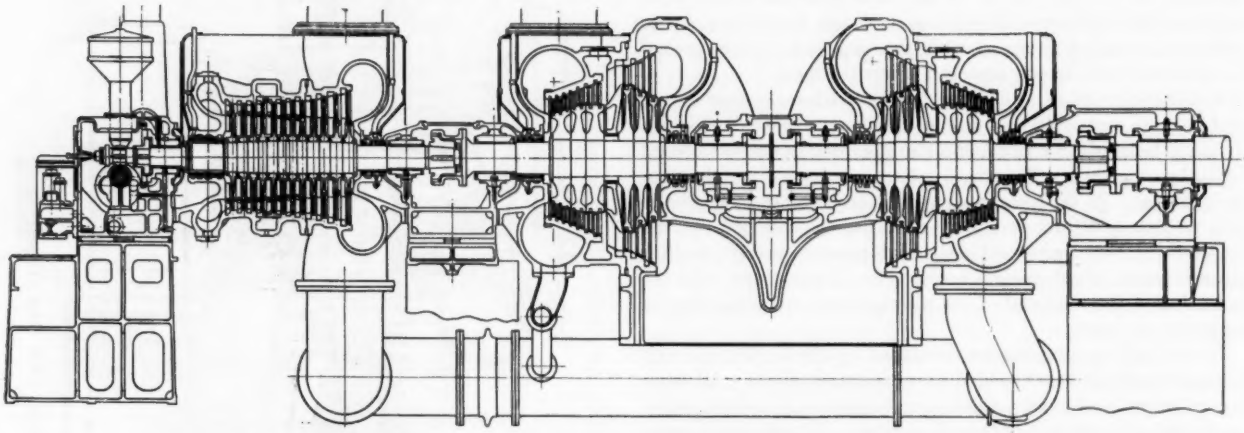

FIG. 16 30,000-KW THREE-CYLINDER TURBINE, 3000 RPM (ENGLISH ELECTRIC COMPANY)

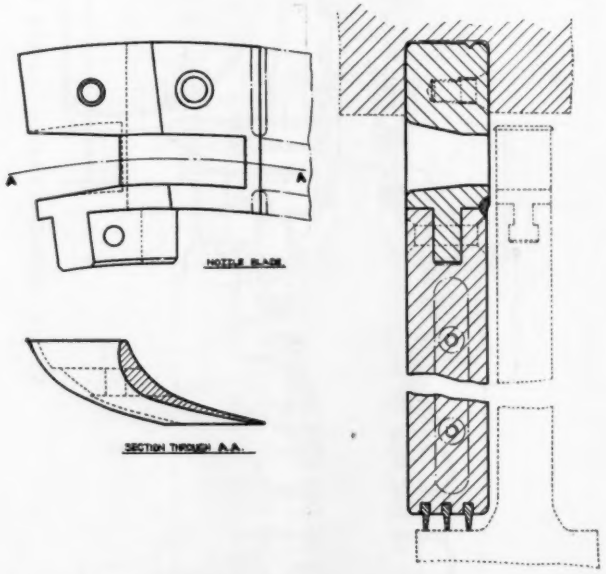

FIG. 17 BUILT-UP DIAPHRAGM CONSTRUCTION (ENGLISH ELECTRIC COMPANY)

As the two turbines are independently supported, the alignment of one line is not likely to be disturbed by variations of temperature in the other. The power distribution between the two units can be chosen to suit the conditions, as it is subject to no special limitations, so long as the high-pressure exhaust is kept within reasonable dimensions. In a reheat unit, for example, the distribution would be dependent on the reheater pressure. The layout can be modified to incorporate a high-pressure and an intermediate-pressure turbine driving one alternator at floor level with either a single- or a double-flow low-pressure turbine above. The arrangement lends itself naturally to the use of side exhausts on the low-pressure turbine leading direct into twin vertical condensers symmetrically disposed on either side, as shown in Fig. 19.

Built-Up Rotors. The output obtainable from a unit at any given rotational speed is limited primarily by the permissible stresses in the disks and blades at the exhaust end of the turbine rotor. Increase of capacity must therefore involve the use of materials capable of sustaining higher stresses, or else a modification of design to allow of higher peripheral speeds without an increase in stress. In the past, advances have been made chiefly by means of the former method, improvements in the steels available leading to the use of higher stresses. It seems possible, however, that a stage is being approached beyond which further increases in tensile strength are hardly to be expected—that is, in materials suitable in other respects to be used commercially for turbine disks. Various designers have therefore directed their attention to means of reducing the stress at a given surface speed, and have adopted or proposed forms of rotor construction that enable profile disks without any central hole to be used.

The ordinary theory of the stress distribution in a rotating disk indicates that a very considerable reduction in the maximum stress can be achieved by avoiding a central hole. Actually, however, this advantage is not ordinarily obtained, primarily because the assumption on which the theory is based—namely, that the material is homogeneous—is not fulfilled. With the usual method of forging disks from cheeses cut from a bloomed octagonal ingot, there is always the possibility of axial weakness; consequently, while the stress in a disk with the center bored out can be estimated with reasonable accuracy, that in the solid disk is much more indeterminate.

A method of casting ingots by which segregation in the center can be avoided has been referred to earlier in the paper, and this

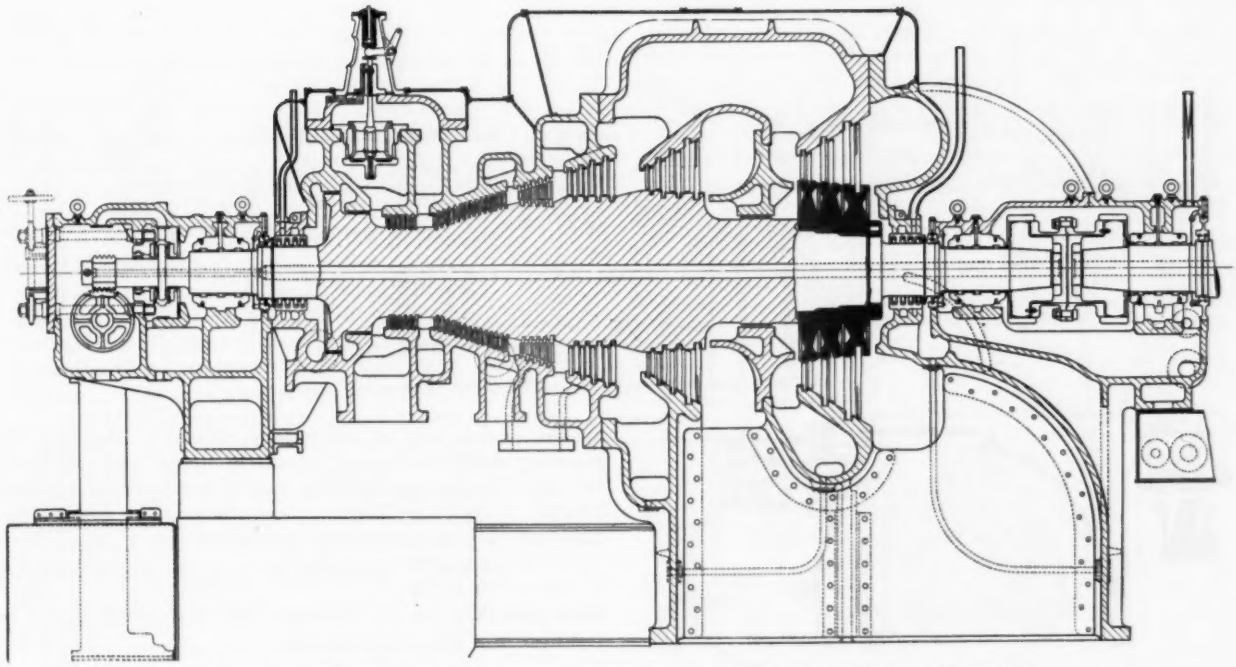

FIG. 18 15,000-KW SINGLE-CYLINDER DUPLEX-EXHAUST TURBINE, 3600 RPM (PARSONS)

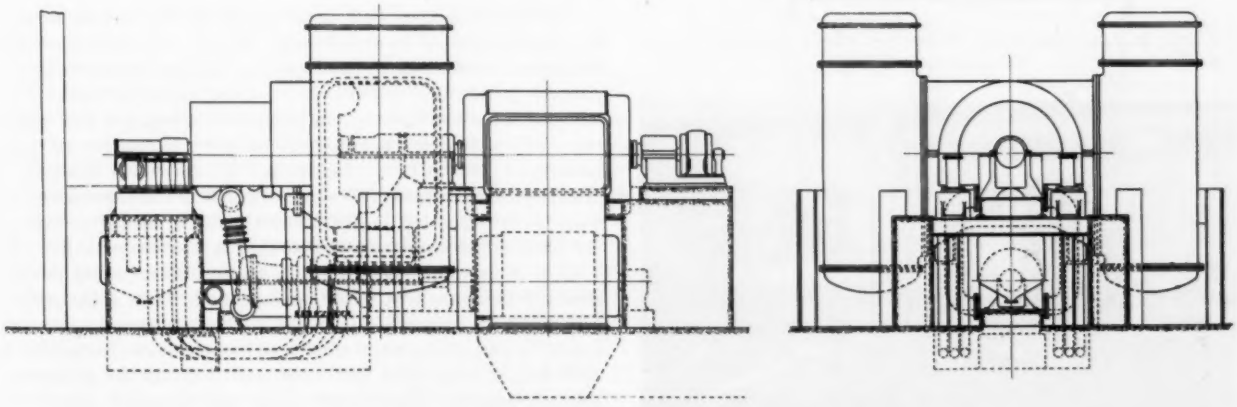

FIG. 19 ARRANGEMENT OF DOUBLE-DECK COMPOUND TURBINE

does make it possible to produce alloy-steel disks reasonably homogeneous throughout. The application of the method to the production of solid disks for built-up rotors does therefore seem to render this a logical development.

Various forms of construction for built-up rotors may be employed. The disks may be bolted together or they may be screwed or shrunk on to spigots. On the Continent, the Brown-Boveri Company has introduced a construction in which the disks are spigoted on each other and welded together around the periphery.

Hollow Blades. The use of solid disks in the manner just described makes possible a higher peripheral speed without an increase in the disk stress. The same result may be achieved in another way by the use of lighter blades. A considerable percentage of the stress in the disk is due to the load of blading which it carries. If, therefore, a lighter form of blade can be employed, the effect on the disk stress will be appreciable, and, what is equally important, there will be a corresponding reduction in the stress of the blade itself.

Attention is therefore being directed to the development of blade constructions in which the material is more economically disposed than is the case with the usual forms of solid-steel blades. The introduction of hollow blades naturally suggests itself as a means of reducing the blade weight, and various proposals have been made for the manufacture of blades of this type. It is customary in present practice to keep the stress at the root of exhaust-end blades within safe limits by tapering, so that the cross-section at the tip is only a fraction of that at the root. The blade illustrated in Fig. 5 affords an example of this. Tapering of a solid blade has, however, limitations, as a reasonable area of tip section has to be maintained. This is necessary both to obtain adequate stiffness and also to preserve an efficient blade profile. Beyond this point, therefore, a reduction in blade stress could be obtained only by enlarging the root section, which would involve increasing the disk stress. If, however, metal was removed from the core of the blades, a greater reduction in stress could be secured without this disadvantage. There would therefore seem to be considerable scope for the application of hollow blades for this purpose.

Light-Alloy Blades. The use of a suitable light alloy instead of

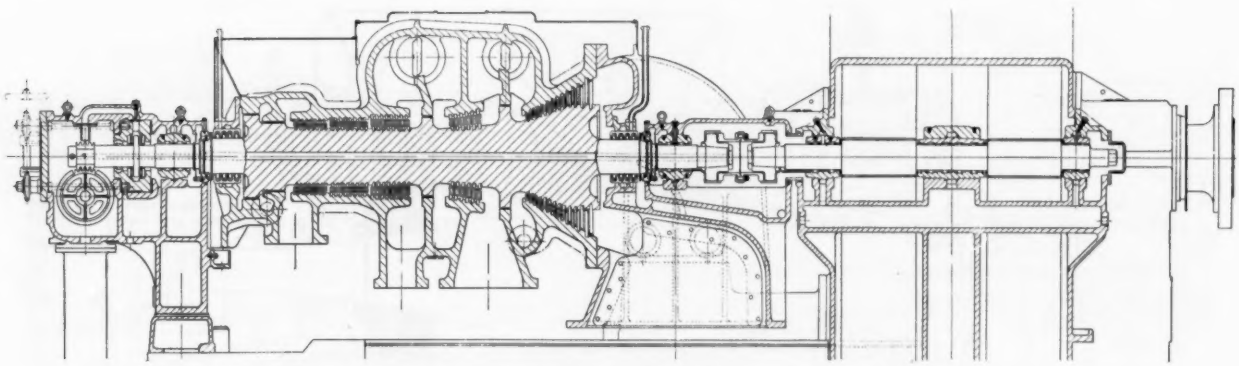

FIG. 20 4000-KW DOUBLE PASS-OFF TURBINE (PARSONS)

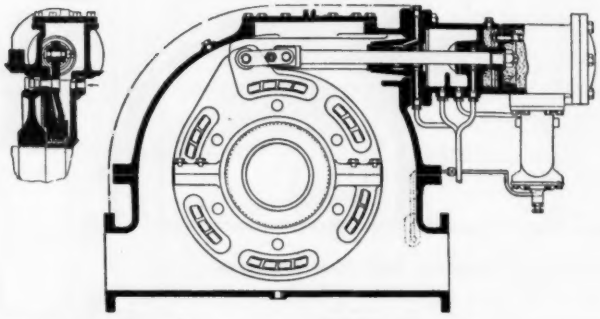

FIG. 21 ROTARY-DISK-TYPE PASS-OUT VALVE (METROPOLITAN VICKERS COMPANY)

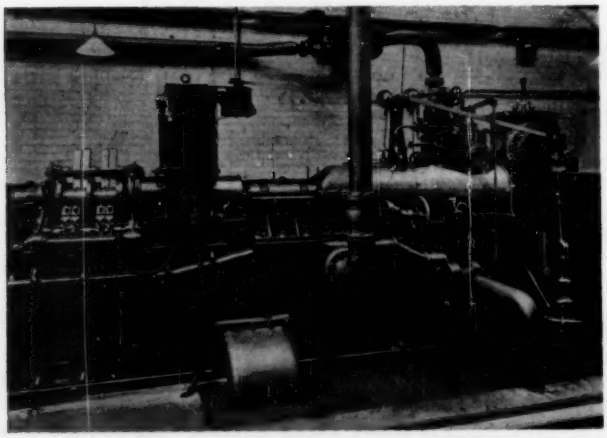

FIG. 22 100-KW TURBO-GENERATOR SET, 1899 (PARSONS)

steel affords another method of securing a reduction in the blade weight. Aluminum alloys are available for which the strength factor, expressed as yield stress divided by density, compares very favorably with that for steels. Similar blades in the two materials would therefore have about the same factor of safety, while the load on the disk for the light alloy would be one-third that for the steel blades, as the density of the former is only one-third that of the latter.

Much progress has been made in recent years in the production of aluminum alloys suitable for moving parts of machines, and their use in various branches of engineering is being constantly extended. The manufacture of blades in these alloys is quite practicable, but their ability to resist corrosion indefinitely in an atmosphere of wet steam is open to question. Another difficulty arises from the fact that the blades would have to be protected against erosion, and no satisfactory method of attaching the necessary shields is at present available. Aluminum solders are not effective, because although a good bond can be obtained initially, corrosion is likely to take place in the solder itself, rendering the joint useless in a comparatively short time. Riveting cannot be employed for a similar reason, as rapid corrosion due to electrolytic action would be set up round the rivets. Until these difficulties can be overcome, light-alloy blades cannot be regarded as a feasible proposition.

PLANTS OF SMALL OUTPUT

Pass-Off Turbines. Industrial plants are for the most part arranged to supply process steam. In the older machines the regulating mechanism for maintaining constant pressure at the pass-off point was accommodated in a separate chest. The whole of the steam had to pass through this chest, and that which was not required for process was returned to the low-pressure blading of the turbine. In present-day machines, however, a much neater arrangement is adopted in which the pass-off control valve is incorporated in the turbine cylinder itself. A typical arrangement of a machine of this type is reproduced in Fig. 20. This is a machine supplied to a paper mill requiring process steam at two pressures, so that two pass-off valves are provided. The boiler pressure is 350 lb per sq in., and the process pressures are 35 lb and 18 lb, respectively. The output of the turbine is 4000 kw, at a speed of 4500 rpm, and it drives d-c generators through gearing. The process-steam valves, which are of the butterfly type, are controlled by an oil-operated servomotor relay responsive to the pressures in the process system, the main throttle valve on the high-pressure steam supply to the turbine alone being controlled by the speed governor.

The Metropolitan Vickers Company employs a rotary disk valve to regulate the pressure in the process main. The disk, which is actuated by a power piston through an oil relay, is provided with ports that control the number of nozzles admitting steam to the low-pressure section of the turbine. If the demand for process steam increases, some of the nozzles in the first low-pressure stage are blanked off, and the heat drop available in the condenser steam is maintained. This arrangement is shown in Fig. 21.

Self-Contained Units. Many of the earliest condensing turbo-generators built by the Parsons Company were arranged as a complete unit, with the turbine and generator mounted directly on top of the condenser and with reciprocating circulating and air pumps both driven by worm gearing from the turbine.

Such a unit, built in 1899, is shown in Fig. 22. So long as the bulk was small enough for the complete unit to be accessible from the floor, this arrangement was retained, but increasing capacity made it necessary to provide a separate operating platform at a

level approximately at the top of the condenser. With still further increase in unit size, two separate floor levels were adopted and so was evolved what is called the condenser basement. The turbine was mounted on the engine-room floor, from which the operation could be performed, while access to the condenser was readily obtained from the basement. The condenser auxiliaries had now become too cumbrous to be driven from the main turbine and were accommodated as independent units in the basement.

This arrangement with the condenser vertically below the turbine became the generally accepted standard for small as well as for large units. In the course of time, however, as developments progressed, the conditions became favorable for a revival of the self-contained unit. A number of factors contributed to this: the dimensions of the turbine and alternator in relation to the output had become very much smaller, condensers had become much more compact, the steam ejector had been introduced and had replaced the bulky reciprocating air pump, centrifugal pumps had become much simpler and more reliable, and mechanical gearing had been developed to a high pitch of refinement. These conditions rendered possible a closing up of the complete equipment into a compact and simplified unit, occupying much less space and requiring much less foundation than the older type. Development of various forms of the self-contained type of plant has proceeded rapidly and it has now become general for units up to about 3000 kw capacity, such as are largely used in industrial plants in England. A considerable number are also being exported for the supply of power to small towns and sparsely populated districts in many other countries, where the saving in cost of buildings and foundations and the ease of transport make them very attractive.

Fig. 23 shows a typical arrangement of a 1500-kw uniplane set manufactured by the Parsons Company, and, as the name implies, the unit is arranged in one horizontal plane. This arrangement has been developed with a view to obtaining ease of erection and maintenance, and simplicity of operation to the greatest possible degree, and has proved extremely successful in a large number of installations. The turbine, which is of the impulse-reaction type, is solidly coupled to a helical creep-cut pinion and so designed that the end pressure of the turbine spindle is toward the turbine exhaust and balances as nearly as possible the end thrust from the gear. A pivoted pad thrust block is fitted to carry the small end thrust that remains and to maintain the axial alignment. The gear wheel is also located by a pivoted pad thrust and is solidly coupled to the alternator rotor, which is of the salient, pole type.

The exhaust portion of the turbine cylinder, the bottom half of the gear case, and the bedplate are made in one casting so that the turbine and gear alignment are not affected by movement of the foundations, the design of the combined casting being sufficiently rigid to withstand distortion. The bedplate also forms the oil tank, and the oil cooler is accommodated within it. The high-pressure portion of the cylinder is a single steel casting, which incorporates the nozzle box and high-pressure blading and in addition the bearing, gland, governor, and oil-pump housings. There is no separate steam chest, but the combined runaway and stop valve and the oil-relay-operated governor valves are mounted in the nozzle box itself. The arrangement of this part is shown in Fig. 24.

The circulating and extraction pumps are driven by a worm gear from the end of the pinion shaft, the arrangement being such that the turbine, gearing, condenser, and all auxiliaries form one complete prime-mover unit, and are quite independent of the apparatus that the turbine has to drive. This may be an alternator or d-c generator, a pump, blower or rope pulley for a mill drive, according to the requirements.

Geared units are adopted for outputs up to 2000 kw, for straight condensing machines, and up to approximately 2500 kw, for

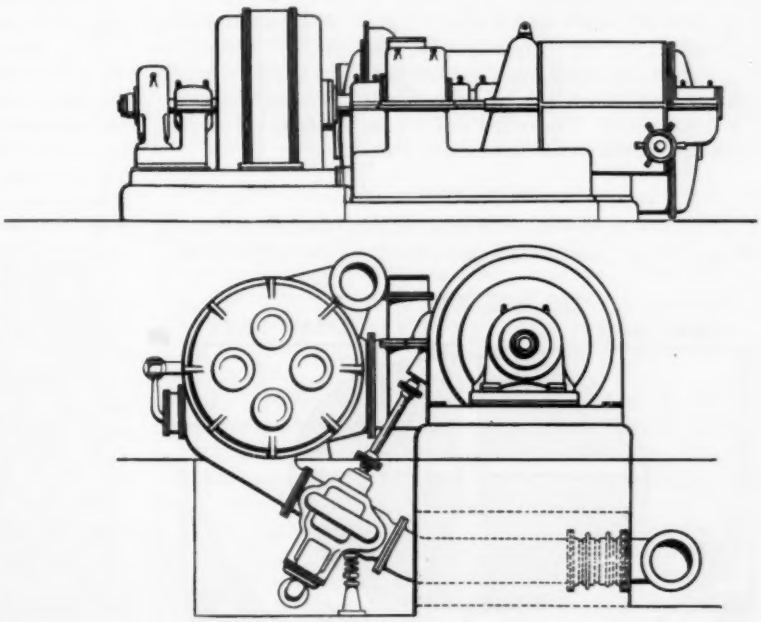

Fig. 23 1500-Kw Uniplane Set

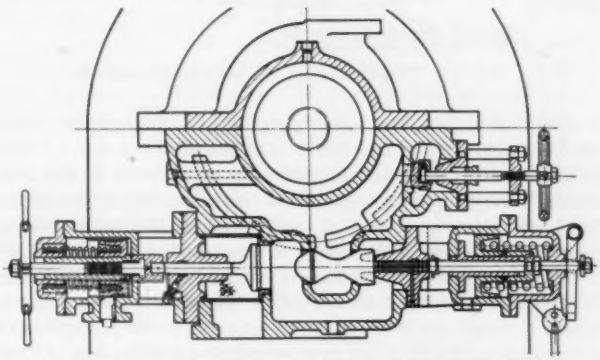

Fig. 24 Arrangement of Uniplane Control Gear

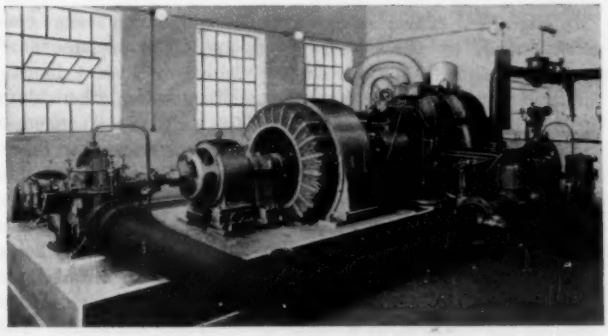

Fig. 25 1000-Kw Self-Contained Unit (Metropolitan Vickers Company)

pass-off machines, although the latter naturally vary somewhat with the steam conditions. Above these outputs the units are direct-coupled for either 3000 or 3600 rpm, and in the case of direct-coupled machines the auxiliaries may be driven either by an extension of the exciter shaft or by gearing from the turbine shaft in a manner somewhat similar to that already referred to.

Somewhat different schemes are adopted by other manufacturers. In Fig. 25 is shown a unit manufactured by the Metropolitan Vickers Company. This figure is taken from a photograph of a 1000-kw machine and is typical of the arrangement standardized by the company. In this case the turbine is supported on the condenser, its center line being at such a height that the gear pinion can be conveniently arranged above the slow-speed wheel. The exciter and circulating pump are coupled in tandem on the end of the generator shaft.

Condensers

The growth in the size of generating units and the persistent demand for more economical generation have led to the advance

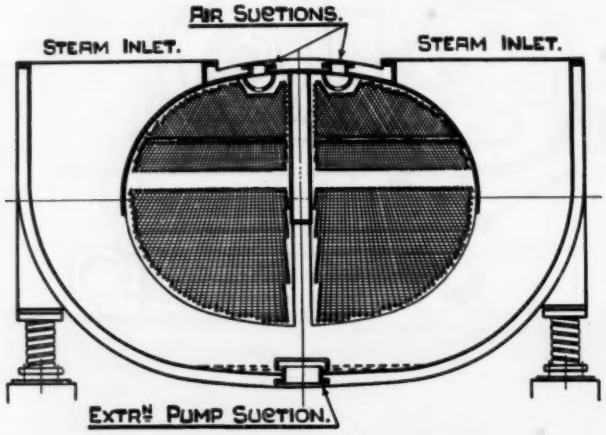

Fig. 26 Double-Inlet Condenser (Parsons)

in steam conditions, and to the progress of turbine design which has been reviewed in the earlier sections of the paper. These same factors have caused attention to be directed to the condenser, a very important section of the plant, which previously had been rather neglected, at least so far as the application of scientific principles to the design is concerned. A large number of new and revolutionary designs have been introduced during the last few years that seek, first, to improve the steam distribution through the tubes so as to make a greater proportion of the cooling surface effective and, second, to avoid the loss of heat that results from cooling the condensate below the vacuum temperature.

In Fig. 26 is shown an arrangement adopted in recent condensers made by the Parsons Company. The example illustrated is designed for a double-flow turbine with two exhausts; the tube nest is separated from the steam space on either side of the shell by a baffle, which extends the full width of the condenser in the upper portion. The steam entering at the top has therefore to pass straight down to the lower part of the shell and in so doing is spread out laterally, so that when it enters the tube nest it is distributed over the full length of the tubes. The flow over the tubes is in an upward direction, the air suctions being right at the top. The air-extraction ports are arranged so as to produce a uniform suction across the condenser, and to maintain the distribution of steam or vapor over the tubes. The condensate falls to the bottom against the steam flow, so that its temperature at extraction is not reduced below the vacuum temperature. On the circulating-water side the condenser is designed for two flows, the first flow being of course at the top and the second at the bottom.

An incidental feature of this form of condenser is the protection of the top row of tubes from the direct impact of water drops thrown off at high velocity from the tips of the last row of revolving blades in the turbine. Tubes punctured by the erosive action of these drops have been a frequent source of trouble, so much so that some power-station engineers have made a regular practice of plugging or fitting dummy tubes in the top row.

The popularity of the single-flow condenser in America has been the subject of some comment in England, where two-flow condensers have been almost invariably employed. This would, however, seem to be due to a difference of conditions rather than to a radical divergence of practice. At all events, in the cases which the author has had occasion to consider, the conclusion has always been in favor of the two-flow arrangement. Each type may have several points in its favor, and a small difference in conditions may influence the choice between them.

Generally speaking, a single-flow design means a smaller surface and longer tubes, compared with a two-flow for the same duty. For condensers of very large capacity these are advantages, as they result in a better proportioned and more easily accommodated shell. For small units, however, long tubes are undesirable because it is not usually convenient to provide the clear space necessary for their withdrawal, and also if the condenser is close to the turbine exhaust the steam will have to spread too suddenly for the tubes to be properly covered.

The single-flow condenser, with its relatively short path and large area through the tubes, requires a much greater quantity of circulating water than a two-flow to give a reasonable water velocity. This is an important consideration where, as is frequently the case, a long pipe line is unavoidable. Although the power absorbed in pumping the water through the condenser itself is not increased, a much greater loss in the pipe line has to be faced or else the expense of larger pipes and sluice valves has to be incurred.

The design of single-flow condensers does present one difficulty not encountered in the multi-flow type. The temperature of the cooling water rises continuously in its passage from the inlet to the outlet end of the tube nest. Hence, the condensing capacity is greater at one end than at the other, and the natural distribution of steam is far from uniform. To provide adequate steadiment for the long tubes of a single-flow condenser, it is necessary to employ several intermediate supporting plates, and the effect of these is to sectionalize the tube nest and to interfere with the free distribution of steam. Further, the non-condensable gases from the hotter end will not be so effectively cooled, unless some special arrangement is adopted to make them traverse a section of the tubes in the cold part before reaching the air-pump suction.

The general problem of tube corrosion still remains a perplexing one, but definite progress has been made in the production of materials more resistive to its ravages. Cupro-nickel with a nickel content of not less than 30 per cent has been used with very successful results. Very promising experience, however, has been obtained also with the aluminum-bronze alloys more recently introduced, and these are likely to be more generally used than cupro-nickel. The difference in the initial cost of the two materials is so great that, even if the cupro-nickel tubes should prove to have an appreciably longer life, it may still be more economical to employ the aluminum bronze. It is only on account of the high initial cost of the nickel alloy that it has not been generally adopted.

The most usual practice for tube fixing in large condensers is to expand the tubes at one end and to retain the packed ferrule at the other. Generally, expansion is adopted at the inlet end, as it

gives a rather smoother bell-mouthed inlet than the ordinary ferrule. In two-flow condensers, therefore, half the tubes are expanded into one tube plate and half into the other. The practice of expanding the tubes at both ends has not been used in England. The principal argument used against it is the possibility of extensive damage to the condenser should the unit, through some accident, go over to atmosphere. Although such an occurrence may be extremely improbable, the risk of it cannot be altogether ignored, and the use of automatic devices to shut down the machine on a falling vacuum is undesirable, because it may cause an interruption in the continuity of supply.

The use of steel plate instead of cast iron for condenser shells was introduced some ten years ago and soon became generally accepted practice. A riveted construction was at first employed for these steel shells, but more recently riveting has in its turn been replaced by welding, and welded shells are now used for all sizes of condensers.

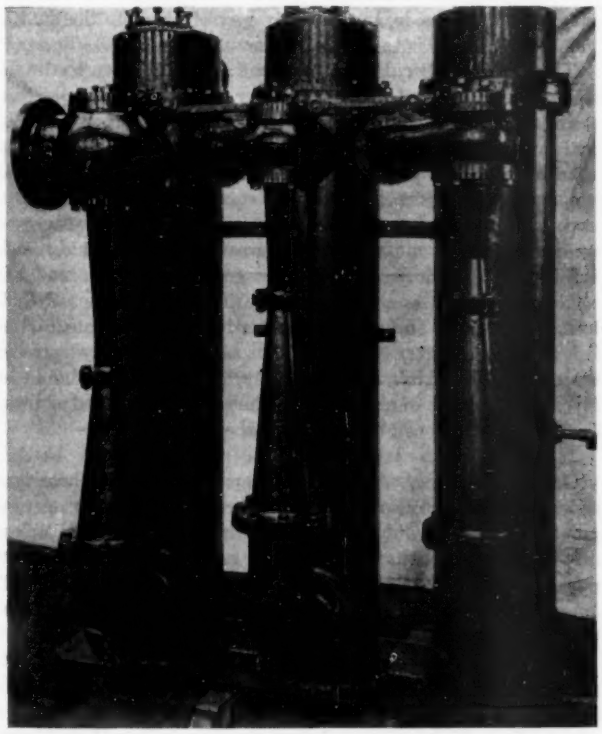

FIG. 27 THREE-STAGE EJECTOR, WITH FABRICATED STEEL SHELL

The great strides made in welding practice and the general tendency to introduce fabricated steel in all branches of power-plant work have led also to the use of steel for water boxes and end doors, particularly for cases where the circulating water is fresh. For salt water it is necessary on account of corrosion to use much thicker plate than otherwise would be required; consequently, the fabricated construction does not possess quite such a definite advantage over the casting.

Another interesting application of fabricated construction is furnished by its use for the condenser elements of air ejectors. An illustration of a three-stage ejector of this type is given in Fig. 27. The three condensers have cylindrical steel-plate shells built up as one unit, but each condenser has a separate water box and tube element. The entrainment chambers and diffuser tubes of the ejectors are supported on facings on the condenser shells. It has become usual to employ three-stage ejectors on the larger plants in preference to two-stage, because with a high vacuum an appreciable saving in the ejector-steam consumption can be effected in this way. For a vacuum of 29 in. the saving amounts to 30 per cent on the consumption of this auxiliary, one of the many small items that assist toward the attainment of a good overall economy of the plant.

Discussion

A. G. CHRISTIE.[3] The Society has had unusually good fortune in securing this paper from so well known a British engineer and particularly so in view of his position in the pioneer firm of British turbine builders. His comments upon current practice have particular weight in view of the long and varied experiences of his firm, C. A. Parsons & Co. Comments on this paper must therefore express variations in practice rather than differences in principles.

The author considers the development of the Grid System in England under the direction of the Electricity Commission. The writer's observations are that the British people as a whole are not as electrically minded as the Canadians. When the use of electricity becomes more general, the consumption per capita will rise rapidly, which will necessitate the construction of large power stations in Britain comparable with the largest in the United States.

A visitor to England is struck with the large number of firms building steam turbines for power-plant use. There are at least seven building the larger units. In the United States there are only three firms building large turbines, and from 1929 to 1931 one of these firms sold about two-thirds of the total output.

An outstanding characteristic of British practice has been the development of tandem units of large capacity at 3000 rpm. The largest tandem unit at 3600 rpm in America is 15,000 kw. The British, however, have several 30,000-kw units at 3000 rpm and can build up to 50,000-kw units at this speed. American engineers have favored single-cylinder units at 1800 rpm, although some efficiency may be sacrificed by their use.

In the matter of initial steam pressures, American practice favors 1200 lb in place of 600 lb for reheating plants. In fact, some engineers hold that the 1200-lb plant can be built for no more money than the 600-lb station. Through the data in a recent N.E.L.A. Report on Higher Steam Pressures and Temperatures it is shown that the average performance of 1200-lb stations over a range of capacity factors is about 8 per cent better than the 600-lb plant at the same capacity factors. Mr. Gardner only allows 5 per cent for this difference. British engineers have in some cases used higher initial steam temperatures than employed in the United States. However, the value of high steam temperature is now recognized here, and new stations will undoubtedly use steam temperatures of 850 to 900 F.

American engineers are keenly interested in all questions dealing with creep in metals. The figures of allowances quoted by Mr. Gardner are in general in close accord with American practice. We are experiencing similar difficulties with bolting materials.

While reheating is an element of many American stations, it is now thought that practice may be altered in new plants. Our engineers favor straight flow to reheating units. Increased steam temperatures will allow of the use of higher pressures without reheating and with moisture at exhaust within safe limits.

One is tempted to ask whether any station can be considered a base-load station. The late Col. P. Junkersfeld held that every new unit was a base-load unit, but only until the next unit supplanted it. Recent data indicate a rapid decrease in capacity factors of most turbines after the sixth year of operation, even in those considered originally as base-load units, and comparatively

[3] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

low capacity factors after the tenth year. The average capacity factor for the whole useful life of a turbine appears to be much lower than generally assumed. Therefore one may rightly question whether any turbine should be purchased to serve as a base-load unit.

Steam reheating only effects a thermal gain of about 2 per cent over no reheating. However, it improves the moisture content at exhaust, and this is a practical benefit of considerable value. As many as five bleeder heaters have been used on American turbines. Present practice favors the use of three or four combined with steaming economizers. This combination leads to lower cost plant of high economy. Deaeration in special open-type heaters just before the boiler-feed pump has been found preferable in American practice to deaeration in the condenser as favored by Mr. Gardner.

Erosion of the last rows of blades has now become a major problem in American stations and is probably assuming serious proportions abroad. Mr. Gardner's researches on erosion form an outstanding contribution to our knowledge of the subject. A student of the writer made a special study of this subject for the N.E.L.A. last winter and developed some interesting information. The per cent of moisture at the last row of American turbines may be as high as 14 per cent, whereas abroad this is often limited to 10 per cent. The greatest difficulty is experienced with blading with tip speeds of 1000 fps or over. Parsons blading with relatively lower steam velocities has been more subject to erosion than impulse blading, suggesting that supersaturation was less pronounced in the Parsons than in the impulse blades. Devices to drain off moisture have been only partly effective due to the nature of the formation and the path of the water droplets. Other experimental work at Johns Hopkins University indicates that no separating device can be very effective. Comparatively little information is available in America on the development of erosion-resisting steels, and Mr. Gardner's data regarding the performance of hardened tool steels are particularly welcome.

The writer always has been a strong advocate of water-sealed glands. Early experiences with foggy engine rooms and dripping roofs in Northern plants during winter weather was sufficient warrant for the use of water-sealed glands to prevent any loss of steam into the operating room.

British practice favors multi-cylinder units. In America the higher costs of building and equipment have led engineers to select single-cylinder units. One regrets that Mr. Gardner has not included some performance figures on the multi-cylinder type that might be compared with American results.

Mr. Gardner marvels at the use of single-flow condensers in America. These are only purchased when it is evident that their use will lead to the highest over-all economy. American practice is tending toward condensers with tubes rolled at both ends. These are proving cheaper, tighter, and more reliable than packed tubes. When tubes are properly bowed and supported, no difficulty will be experienced should the condenser lose its vacuum.

Mr. Gardner's presentation of British practice leads one to question many of the currently accepted methods in America. A study of these conditions and the adoption of features of British practice will lead to the construction of better and more reliable American units.

M. H. Adams.[3] In both papers on modern turbine design there are one or two points, from the view of one who has to operate and maintain these machines, that the writer would like to raise.

Turbine designers have not given enough consideration to the design from the operator's standpoint. A chief complaint with the modern turbine is that the most important parts of the machine cannot be examined without considerable time, trouble, and expense. In the old days, with smaller units, dismantling for examination was not a very serious matter, but it becomes increasingly difficult as the size of the machine increases, and today the lifting of the top half of the turbine for examination is a laborious and costly business. In the event of any slight noise occurring in the machine or a sudden temporary roughness in running, one has to decide whether it is necessary to open up and put the plant out of commission or whether to run the risk of something far more serious occurring.

There should be no great difficulty in arranging suitable inspection doors or plugs through which the whole of the blading or at least the banding could be examined. Any extra cost involved would be gladly paid by generating engineers, as this cost would probably be saved many times over during the life of the machine. The design of most machines could be cleaned up very considerably from the outside, but the only way of bringing this matter home to designers is to show them actual examples.

There does not seem to be sufficient attention given to the design of the oiling system. In a number of designs it is impossible, owing to pockets, to drain out the whole of the oil and sludge, and the arrangements made for allowing settlement during operation are generally poor. The chief fault lies, however, in that no adequate provision is made for the collection of sludge. Our experience shows that the centrifuge, while removing water and solid matter, does not remove any great quantity of sludge. It is found that the only satisfactory way of collecting the sludge is in the colder part of the oil coolers. The sludge generally collects on these cold surfaces in comparatively large quantities, but it is a difficult matter to clean coolers satisfactorily as at present designed. The writer feels, therefore, that attention should be given to the design of oil coolers, so that they can be used as traps for the sludge and can be speedily and easily cleaned.

Gerald Stoney.[4] These two papers show that there is a general tendency toward increased steam temperatures up to a point where creep and embrittlement may cause trouble unless materials are used that are not only more expensive and often more difficult to work, but also about which comparatively little is known as to their properties when subjected to high temperatures for long periods.

Even as it is, nine-tenths of turbine troubles are caused by expansion, etc., due to temperature, and a point often ignored is that with high temperatures increased clearances have to be allowed for safe running, and thus the gain due to these higher temperatures is to some extent discounted. The usual rules for the gains due to temperature are with the same clearances. Even if the original clearances are fine, the turbine will in time wear itself to larger clearances with high temperature than with low.

Pressure, per se, does not cause such troubles; for example, in hydraulic machinery, where very high pressures are common, there is little trouble.

With moderate temperature, say 750 F, and high pressures, the wetness in the exhaust is large. This can be avoided by reheating; but even without this, by draining and protecting the last rows of blades by hard shields of high-speed tool steel, as described by Mr. Gardner, the trouble due to erosion by water can be completely avoided, and there is no reason, apart from the losses due to wetness, for wetnesses of 20 per cent or even more not being allowed. Many consider that the extra cost and complication of reheating is not worth the extra economy of fuel, and it has always to be remembered that simplicity, reliability, and ease of

[3] Engineer, Generating Department, Lancashire Electric Power Company, Stoneclough, England.

[4] Newcastle-on-Tyne, England.

working count for a great deal and that on an average coal is only 16 per cent of the cost of generation while capital charges amount to 45 per cent. (See *World Power*, January, 1930, p. 43.)

In this regard the advantage of large overloads for turbines has to be considered, such as the Hell Gate turbine of 160,000 kw is able to do. Here down to half or even third load there is good economy. The advantage of such large overloads is seen when it is remembered that in a typical case with a 40 per cent load factor over the year, a load of more than 55 to 60 per cent of the peak load lasts only for about 10 per cent of the total time and accounts only for some 6 to 7 per cent of the whole output. By using turbines with large overload capacities, important capital savings can be made with a very small increase in the coal bill. This was fully dealt with in a paper by Mr. I. V. Robinson at the World Power Conference, Tokyo, 1929, in one by the late Sir Charles Parsons and Mr. R. Dowson at the similar conference in Berlin, 1930, and in an article by the writer in *Engineering* of February 13, 1931.

In this country 50 periods is general, requiring 3000 or 1500 rpm, and as the Parsons constant, $K = NR^2D^2 \times 10^{-9}$, is the same for both, it follows that, representing the volume of the blading by ND^3, the volume is $^1/_4$ for 3000 rpm as compared with that required for 1500 rpm, meaning a large saving in turbine costs and weights. Sizes of 40,000 kw at 3000 rpm can now easily be made, and it is probable that this limit will increase in the future, while in this country sizes of from 50,000 to 75,000 kw are being adopted at 1500 rpm. It is a question whether it would not be better to have more turbines at 3000 rpm rather than somewhat fewer at 1500 rpm, considering the probable lower cost due to the reduced weights. Also the lighter parts make them more easily handled and more quickly overhauled, and the time for running up and getting on load is less. A point to be remembered also is that it is much easier to get reliable forgings and castings of moderate size than very large ones.

H. M. Martin.[5] The paper by Messrs. Alden and Balcke constitutes a remarkable synopsis of present power-station practice in America, and must have involved much labor in the collection of data and much thought in arranging it so clearly and concisely. The only point to which one might be inclined to take exception is the assertion that the over-all efficiency ratio has been found to serve effectively as a basis for comparison of turbines operating under varying conditions, and as a matter of fact this claim is largely discounted a few lines later, where it is emphasized that a direct comparison cannot thus be made between two machines operating under widely different conditions. In times past, the efficiency ratio had the merit of being easily computed, but this, its sole advantage, has largely disappeared with the introduction of progressive feed heating and of reheated steam. As one result, estimates of thermodynamic efficiencies have been apt to vary with the fancy of the individual engineer. M. Darrieus, an able French engineer, has accordingly suggested a modified method of computing thermodynamic efficiencies. This consists essentially in debiting the turbine with the theoretical available heat of all steam entering it, and crediting it with the available heat of all steam withdrawn from it. The balance, divided by the difference between the total heat entering and leaving the turbine (i.e., the indicated work), is the Darrieus efficiency. This procedure leads to perfectly definite results, but it is difficult to see any utility in the figures obtained. The Darrieus efficiency does not represent either the thermal efficiency of a turbine or its efficiency as a "hydraulic engine."

The discussion of blade erosion in Mr. Gardner's paper is illuminative. In 1916 it was officially stated that blade erosion was unknown in the British Navy, owing no doubt to the low steam speeds then ruling. The importance of speed was clearly shown at quite an early date, when the ordinary brass alloy used for reaction blading was adopted for the blades of a small-velocity compounded turbine. The blades were destroyed in a fortnight's run. In these early days, however, the steam commonly had solids in suspension owing to the use of hard feedwater. It was not clear, therefore, whether the damage was due to this suspended matter or to droplets of water. It is now evident that the latter constitute the real destructive agent.

It is of interest to note that in the absence of any cushioning effect of the steam in which the droplets are suspended, the stress produced by impact on a blade is independent of the size of the drops. The free distortion of the latter is resisted by the viscosity of the liquid, and the rate of distortion is independent of the size of the drop. Similar distortions are proportional to the size of the drop, and hence (at a given speed before impact) it takes longer to distort to similar shapes a large drop and a small one. The stresses are all proportional to the rate of distortion, and this rate is the same for all sizes of drop. In practice the cushioning effect of the steam is very important, and by Stokes's law will be inversely proportional to the square of the drop diameter. Actually, some data, for which the writer is indebted to Mr. F. Samuelson, of the British-Thomson-Houston Company, Rugby, show that the effective drop diameter must have been at least $^1/_{16}$ in. in the case of an experiment made by inserting, in a ring of blades, four, equally spaced, which stood $^1/_{16}$ in. above the general level. It was found that the whole of the erosion was concentrated on these four blades.

Mr. Gardner remarks that the "yield point" does not measure the resistance of a material to erosion. The explanation tendered seems, however, inadequate. If pits are present, stresses will be increased, as he states, but the question remains as to how such pits originate. It seems unlikely that a pit of molecular dimensions could be effective.

It would be of great interest and of considerable theoretical importance to obtain really accurate measurements of turbine efficiencies with and without stage-by-stage drainage. In the one case, for which the writer has data, the efficiency seemed quite unaffected, but the precision of the test was insufficient to justify a definite conclusion.

W. F. Ryan.[6] The main objective of the Power Division in regard to the papers by Gardner and by Alden and Balcke, presented at the Bigwin meeting, was to bring out and to *explain* the differences in trends of design in England and in the United States. The papers and the discussion developed the differences adequately, but there was almost nothing to explain these differences.

An editorial in *Engineering* (London) for September 16, 1932, entitled "Steam-Turbine Problems," furnishes a most valuable discussion of these papers. The first three paragraphs of this editorial are as follows:

> American engineers have been more tolerant of high leaving losses in their steam turbines than has generally been considered good practice in this country. An interesting, if partial, explanation of this is to be found in the comprehensive discussion of present-day American practice given in the paper by Messrs. Alden and Balcke, which was reprinted in our issues of July 29 and August 5 and 12. It was there pointed out that a leaving loss of 5 per cent to 6 per cent at full load, under American winter conditions, may correspond to an average loss, taking the year round, of about $1^1/_2$ per cent to 2 per cent. The high summer temperature offsets the winter's cold so that apparently the vacuum averaged over the year does not

[5] *Engineering*, London, England.

[6] Mechanical Engineer, Stone & Webster Corporation, Boston, Mass. Mem. A.S.M.E. Member of Executive Committee of Power Division.

exceed some 28¼ in. Here, climatic conditions are much less extreme, and though we seldom can get circulating water at 35 F, which is customary in Chicago during the winter months, summer temperatures, at once high and sustained, are equally unusual. Even with our mild winters, however, stations like Brimsdown secure an average vacuum during that season of 29.1 in., the average for the twelve months ending on December 31, 1931, being 28.86 in. The still higher annual average of 28.92 in. was, Mr. Donaldson informs us, recorded during the previous year. The average air temperature during the months October to March, both inclusive, is about 45 F in the London area, being lowest in February, when it averages about 5 deg less. The average for the other half of the year is 59 F. The warmest month is August, in which the temperature averages nearly 4½ deg more. The mean winter temperature of New York, on the other hand, is given as but 22 F, the summer mean being 72 F, and the annual average 52 F, which is only 1 deg more than the London average. American engineers have, therefore, to deal with much more extreme conditions.

At the same time there is, we think, reason for believing that we still maintain our lead in the design of surface condensers, which was secured by the early work of Sir Charles Parsons, and has been promoted since by various practical and theoretical investigations. It was here, apparently, that the plan of dividing up the various resistances to heat flow was first introduced, and this has certainly led to clearer conceptions of the phenomena involved. As indicating the hazy ideas previously prevalent, it may be noted that Stanton, as the result of his own observations on actual condensers, came to the conclusion that the steam pressure was a highly important factor. As matters now stand, stations using cooling towers record vacua of about 28½ in. with circulating water supplied at 75 F.

Messrs. Alden and Balcke state that single-pass condensers are most commonly used in the States. This is, perhaps, partly due to the large size of the units generally installed. With small outputs, several passes may be required to get the required combination of a good water speed and adequate cooling surface. Thus the small condenser described in a paper read before the Junior Institution of Engineers by Mr. J. M. Newton, in 1912, had six passes. It was coupled up to a Brush turbo-generator rated at 300 kw. A vacuum of 28.8 in. was obtained with a circulating water speed of only 3.4 ft per sec and an inlet temperature of 48 F, rather over 8 lb of steam being condensed per square foot of cooling surface.

Author's Closure

Professor Christie draws attention to the fact that in Great Britain the consumption of electricity per capita is still relatively low, and it is encouraging to hear the view that a rapid expansion may be expected. Nevertheless, there are in England, as he points out, several large firms that build generating plants, and there seems little prospect that the requirements for the home market will be sufficient to keep the factories of all these firms employed.

Regarding the discussion on steam pressures, there is little doubt that, as conditions exist today in England, a 1200-lb installation would cost more than a 600-lb one, but it is safe to assume that costs will tend to level up. In the past, every advance in steam conditions has at first been hampered by its higher initial cost, but this is a temporary phase, and as the use of the higher conditions has become more general, the cost of the installation has gradually adjusted itself to an economic level. Professor Christie's remark that "Some engineers hold that the 1200-lb plant can be built as cheaply as the 600-lb" suggests that in the States this condition has already been reached.

In comparing the difference in economy of the 1200-lb and 600-lb installations, the figure of 5 per cent, given in the paper, represented the theoretical difference in heat consumption of the turbines. Since the paper was written, the author has seen the operating data published by the N.E.L.A., which indicate a difference in overall performance of 8 per cent. It would be valuable to have a complete analysis of the comparative figures showing how this difference of performance is made up—whether it is all in the turbines or whether it is partly accounted for by other factors, such, for example, as improved boiler efficiency.

Dealing with the problem of blade erosion, Professor Christie notes that reaction blading has been more subject to erosion than impulse blading. This is in accordance with what might be expected from an examination of the velocity triangles for the two types. In the case of the reaction blade, the velocity of impact with the water drop is greater for a given blade speed. The same factors which make an impulse blade less liable to erosion, however, also make it more difficult to protect an impulse blade by the method of shielding described in the paper.

Mr. Martin raises the question as to how pits in the surface of a blade originate in the initial stages of erosion. An examination of the surface of any commercial blades under a reasonable magnification will show that there is no shortage of irregularities of sufficient dimensions to start the action, even though, as appears to the eye, the blade has a polished surface. It is not practicable to produce commercial blading in which the irregularities are reduced to anything approaching molecular dimensions. Even if there were no such irregularities present in the first instance, they would soon be produced in service by the sand-blast action of minute solid particles in the steam or by surface oxidation.

With regard to the size of drops, the author's calculations indicate that in the exhaust of a high-speed reaction turbine the largest drop that can persist in the steam stream is only a few thousandths of an inch in diameter. (Strictly this applies only to the drops that leave the blade edge with little or no velocity, but it is these drops that produce erosion.) Owing to the higher steam velocity in a pure impulse turbine, the drops should be considerably smaller than those in the case of reaction.

Mr. Adams' remarks, in which he draws attention to features of design that should be improved, are particularly welcome, as real progress in design can be achieved only by eliminating the defects that the experience of the operating engineer brings to light. With reference to the provision of means of sludge collection and removal from the lubricating system, the arrangement adopted some years ago by the Parsons Company is worth mentioning, for it has proved very successful. The main oil reservoir, which is of sufficient capacity to allow of settlement, is made with a sloping bottom and terminates in a sludge trap consisting of a vertical length of straight pipe. A valve is provided at each end of this pipe, the upper one being normally full open and the lower one closed. The angle of the tank bottom is too steep for solids to rest on it, and they therefore slide down and accumulate in the pipe. The sludge, together with any water present, can be drained off easily at appropriate intervals by closing the upper valve and opening the other. A centrifugal or other type of continuous oil filter is of course provided in addition. This draws oil from the body of the tank, and not from the sludge-collecting chamber.

In most lubrication systems the oil coolers are located at the lowest point, and this may account to some extent for the accumulation of sludge in them. Some form of sludge trap, such as described, could be incorporated with the coolers.

Dr. Stoney questions the wisdom of adopting higher steam temperatures. It is of course true that a large percentage of turbine troubles is due to temperature effects. Advances in temperature have in the past always been attended by new or aggravated expansion troubles, and sometimes by quite unforeseen difficulties. For example, at one period much trouble resulted from growth in cast iron, a phenomenon which had not previously been understood. Nevertheless, in each case the difficulties have been overcome and the advantages of the development have eventually been realized, and this affords the justification for further advances. For the time being, however, temperature limits seem to be rather definitely settled by the known physical properties of the materials available.

FSP-55-4

Steam and Power in the Bleached-Sulphite-Pulp Mill

By W. R. GIBSON,[1] PORT ANGELES, WASH.

Methods of effecting economies in the use of steam in the paper industry are given, together with possibilities of water saving. After a brief description of the processes in a sulphite mill, a table is given of the probable requirements in steam and power for a 150-ton mill. The possibilities of combining the operations of a pulp mill and a sawmill are stated, the sawmill having a surplus of waste wood for fuel and of low-grade wood for pulping and usually exhausting large quantities of steam to atmosphere. The effect on refractories of hog-fuel ash is related.

MAKING bleached sulphite pulp involves quite a few operations. A suitable wood, hemlock, spruce, or alder, alone or in combination, is cut into chips 7/8 to 1 in. long, 1 in. wide, and 1/8 in. thick. These chips are cut off in such a way as to open the end grain to aid penetration by the acid in the cooking operation. The chips, screened and free of dust, are cooked in sulphurous acid in a digester 8 to 11 hr at about 70 lb pressure to free the fibers of the ligneous binder. The cooking being completed, the fibers are blown from the bottom of the digester to a blow pit with a vomit stack, the vapors being released through the stack and the spent cooking liquor being drained away through a perforated floor. The pulp is then washed, and is pumped to a mixing tank, where several "cooks" are combined to secure uniformity. From the mixing tank the pulp is passed over (1) knotter screens to remove knots and uncooked particles of wood, (2) rifflers, to remove grit, sand, and heavy impurities, and (3) flat screens, or vibrating plates that have slots from 0.006 to 0.011 in. wide to exclude everything but fibers. A great amount of water is used in all these operations.

The pulp is now passed over deckers or stock thickeners, where the surplus water is removed, and the thickened stock then goes through two or three stages of bleaching, the stock being washed and again thickened after each stage. With the bleaching finished, the pulp is pumped to stock-storage chests. If the pulp is to be shipped, it is run over a machine where the water is removed by (1) gravity, (2) pressure between rollers, (3) suction, and (4) passing over steam-heated rolls. When dried, the pulp is cut into sheets and is baled for shipment.

This brief statement will give some idea of the need for the large amounts of water and steam and power required in a sulphite mill. Assuming a mill of 150 tons' daily capacity, the quantities should be about as given in Table 1.

TABLE 1 STEAM AND POWER USED IN 150-TON SULPHITE MILL

	Steam usage		Power usage
	Old mill, lb per ton	Modern mill, lb per ton	modern mill, kwhr per ton
Acid plant	300	300	2
Digesters	7,000	5,500	...
Unbleached stock	...	...	100
Bleached stock	3,000	1,500	110
Machine drying	7,000	3,800	80
Heating, etc	500	500	15
Total	17,800	11,600	307

The difference in steam consumption between the old mill and the modern mill is accounted for by the improved methods of cooking, the recovery of hot gases from cooking, the increased density of the stock before bleaching, and the improved mechanical methods of removing water from the pulp before passing it over the heated rolls that complete the drying. A recent development is the vacuum drier, with the steam heated rolls contained in a box in which a vacuum of 27 to 28 in. of mercury is maintained, the sheet of pulp entering and leaving the box through ingeniously designed seal rolls, with a resultant saving in steam consumption. Owing to the lower drying temperature, this results in an improved and stronger pulp.

The water required for such a mill would be 15,000,000 gal per day, or 100,000 gal per ton.

The power requirements, as shown, are good average figures for today. There has not been much change in power requirements, the improved efficiency in the use of power having been offset to a great extent by other changes that, while effecting economy or improving the product, called for a further use of power.

The large demand for steam for processing and for power offers an attractive field for the use of high-pressure steam with back-pressure or bleeder turbines or engines, and the changes in this respect have been rapid in the last 10 years.

An interesting possibility of this field is the combining of a sawmill and a pulp mill. The sawmill has a surplus of fuel and of low-grade wood and usually exhausts large quantities of steam to atmosphere. By combining operations, the pulp mill can use in its chipping plant much of the waste from the outside of the log, which makes the best grade of pulp, and also the lower grade lumber for which the sawmill cannot find a profitable market, and can make use of some of the exhaust steam to heat water for feed or process. All waste wood not used for pulp can be used as fuel. Much progress has been made in the economical use of this hogged fuel. Table 2 gives the performance in a plant of this kind, the figures being as accurate as is reasonably possible with a fuel of this character. The figures are for waste hemlock fuel and are believed to show better performance than has been reached previously with such fuel.

The chief factors in obtaining this performance probably are the highly preheated air and the provision for admitting this preheated air as secondary air for combustion. This is admitted as close as possible to the front wall of the dutch oven, through checkerwork in the inside and the battery walls just on and above the normal fuel line. In practice, separate control of this secondary air has not been found necessary.

[1] Resident Engineer, Olympic Forest Products Company. Mem. A.S.M.E. W. R. Gibson was educated in Glasgow, Scotland, and at East London College and University College, London, England. He served three and one-half years in the Royal Engineers, British Imperial Forces, in the World War in France and in Palestine, with the rank of captain. After four years in Canadian pulp mills, he joined the Zellerbach Corporation as power-plant engineer in 1924.

Presented at a meeting of the Western Washington Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Seattle, Wash., December 9, 1931.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 2 PERFORMANCE OF COMBINED PULP MILL AND SAWMILL

Boiler readings at avg rating (max rating, 275%, avg rating, 160%):	
Draft, main breeching, in. of water	−1.4
Drop across preheater, in. of water	−0.8
Drop across last pass, in. of water	−0.35
Drop across second pass, in. of water	−0.1
Furnace draft, in. of water	−0.15
Pit pressure, in. of water	+0.5
Available induced draft, in. of water	−6.0
Flue-gas temperature, last pass, F	560
Flue-gas temperature, after preheater, F	440
CO, per cent	15.3
O_2, per cent	4.6
CO_2, per cent	0.0
Total air, per cent	128
Air temperature to preheater, F	130
Air temperature from preheater, F	410
Flue-gas temperature at stack (after washing), F	350
Evaporation:	
Oil (per barrel), lb	5,000[a]
Hog fuel (per unit of 4700 lb), hemlock, lb	12,000[a]
Avg moisture, per cent	51.5
Feed-water temperatures:	
Cold water, F	50–55
After steam killer (using sawmill exhaust), F	210
After Cochrane heater (30 lb steam), F	250
After closed heater (150 lb steam), F	345

[a] Unit of evaporation = 1000 Btu.

Perhaps the greatest difficulties in operation of such a plant at high ratings arise from the hog-fuel ash attacking the refractories, forming a slag that builds up on the boiler and the superheater tubes so as finally to bridge across the tubes. The effect on the refractories is due to a combination of factors, all tending to lower the fusion point of the firebrick. Some of these are: (1) high moisture content, (2) high alkaline content, (3) presence of tannic acid, and (4) presence of acetic acid. The high CO_2 possible with this fuel appears also to be a factor, and a most destructive action is sometimes set up by carbon monoxide due to local lack of oxygen. Cases of slag fusion forming masses 3 to 4 ft thick have been cured by the admission of secondary air at the proper point; in other cases, firebrick would disintegrate without visible evidence of heat, apparently due to pockets of CO.

There is also the occasional formation of sodium sulphate due to combination of alkaline ash from hog fuel and sulphur from fuel oil burned together or separately in the same furnace. When this happens, even high-grade firebrick will run like molasses, and the engineer may find more damage to his setting in a few hours than normally would take place in months.

An analysis of slag from different parts of a boiler burning hog fuel is given in Table 3, the fuel being salt-water-borne hemlock with oil as an auxiliary fuel.

TABLE 3 ANALYSIS OF SLAG FROM BOILER BURNING HOG FUEL

	Sample from First pass	Second pass	Last pass	Air preheater
Silica, SiO_2, %	1.6	2.2	1.6	1.3
Iron oxide and alumina, R_2O_3, %	7.7	6.4	15.9	8.9
Calcium sulphate, $CaSO_4$, %	4.9	3.2	7.1	5.8
Calcium oxide, CaO, %	11.5	8.7	6.2	8.3
Magnesium oxide, MgO, %	8.1	6.3	5.7	5.3
Sodium sulphate, Na_2SO_4, %	6.0	14.4	6.5	16.3
Sodium chloride, NaCl, %	55.1	52.7	57.8	53.6
Sodium carbonate, Na_2CO_3, %	1.6	1.6	1.3	1.3
Sodium hydrate, NaOH, %	0.3	0.3	...	...
Organic matter, %	0.3	1.3	0.3	1.1
Undetermined, %	2.9	2.9	...	...
Totals, %	100.0	100.0	102.4	101.9
Fusion temperatures:				
First sign of fusion, F	1050	880	1090	880
Complete fusion, F	1500	1480	1450	1440

The formation of slag on the boiler tubes appears to be due to a kind of cementing action by the sodium-chloride and sodium-sulphate particles on the flying ash. In some parts of the boiler the coating will be soft and fluffy and will disperse easily by blowing and even by a change of temperature through opening an inspection door. Under different conditions, however, the mass will build up quite heavily, and if the boiler rating is raised even for a short period, the mass will fuse into a hard but porous slag that is very adherent. This process is cumulative until the space between tubes is bridged.

At normal rating, using soot blowers and taking all ordinary precautions, we cannot operate more than five weeks without shutting down for cleaning; at high ratings this period is reduced to three weeks.

It should be remarked that in the case referred to all logs are sea-water-borne, and the salt content of the fuel, which is mainly the outside and the bark of the tree, is naturally high.

Hog fuel from mills bringing their logs by rail or fresh water is free from many of the characteristics referred to and offers a different problem in many ways.

Discussion

H. W. BEECHER.[2] It is difficult to add to the paper, but a few points might be brought out. The greatest difference in steam consumption of pulp mills, as reported in the paper, is in the drying of the pulp, and this is attributed in a large measure to the vacuum drier. It should be pointed out that great improvements have been made in press rolls and that these improvements may account for considerable of the difference. To illustrate the possible saving from better pressing prior to admission to the drier section of the paper machine, the stock comes off the press rolls between 27 and 32 per cent stock. The pulp leaves the driers at about 94 per cent stock. In an original pound of 28 per cent stock, there is 0.28 lb of stock; in a final pound of pulp, there is 0.94 lb of stock; so that it takes 3.36 lb of original pulp and water to produce 1 lb of pulp at the finish end of the machine, and this contains 2.425 lb of water. Therefore there has been removed 2.365 lb of water in the driers. Comparing this with a machine furnished with 31 per cent stock, the original pulp and water to the machine would be 3.025 lb per pound of finished pulp, of which 2.080 lb would be water, and the amount of water removed in the driers would be 2.02 lb. In other words, a difference of 3 per cent in the percentage of stock in the original material to the driers would bring about a saving of 17 per cent in the steam required to dry the pulp.

The boiler-performance figures in Table 2 are considerably above the average.

In the author's mill nothing but hemlock fuel is burned. It has been the impression that efficient results could not be obtained with hemlock. As a matter of fact, the heat content per pound of dry wood is as high in hemlock as in fir. Wood refuse is usually measured by volume rather than by weighing, and the weight per cubic foot of hemlock on a dry basis is considerably less than fir. If fuels were weighed rather than measured, hemlock would give results closely approximating those obtained with fir. The chief difference would be due to the hemlock as a rule running higher in moisture than fir.

The author has pointed out the difficulty in operation arising from the ash and foreign matter in the hog fuel. His mill is the first one in which an attempt has been made to secure high evaporations with hog fuel made from logs that have been in salt water. The bark absorbs considerable salt water, and the sodium chloride forms a considerable percentage of the ash that lodges in the tubes. The percentage of ash in burning wood is very small, and the sodium chloride thus becomes a high percentage of the actual weight of ash. It is difficult to account for the presence of the sulphate radical, except that around a sulphite mill the waste liquors are discharged into the bay close to the mill pond in which the logs are stored. A further possible source

[2] Manager, Charles C. Moore & Co., Seattle, Wash. Mem. A.S.M.E.

of sulphate radical is that SO_2 may be present in the air in such quantities and in such a state that it combines in the furnace. As approximately 10 lb of air is passed through the furnace per pound of dry fuel, it would not take a very high percentage of SO_2 in the air to provide the necessary sulphur for the sulphur content of the ash.

The writer does not agree that high percentage of CO_2 has any deteriorating effect on the brickwork other than the general increase in furnace temperature resulting from efficient combustion with low excess air. He does not believe that CO_2 can chemically deteriorate the aluminum and silicate oxides forming the refractories.

The slag that forms in the boiler tubes fuses at about 1100 F, and the character of the slag, as deposited throughout the boiler, has varying chemical characteristics, depending upon the character of the gases at the point of deposit. In the front part of the boiler the slag lodges on the tubes in a molten condition. In the back of the boiler, where the gases are comparatively cool, the ash is soft and fluffy and can be brushed off readily.

It might be interesting to notice that the boiler performance figures given in the paper show a combined furnace, boiler, superheater, and air-preheater efficiency of about 60 per cent. This may appear to be poor efficiency to those who are used to dealing with efficiency obtainable with oil and coal fuel, as these are very considerably higher than the average for hog fuel. The difficulty in obtaining high efficiency with hog fuel is due to the high moisture content of the fuel and the high hydrogen content of wood refuse.

FSP-55-5

Economic Balance Between Steam and Hydro Capacity

By K. McH. IRWIN[1] and JOEL D. JUSTIN,[2] PHILADELPHIA, PA.

K. M. Irwin

There is a popular fallacy that hydroelectric development and additional steam-plant generating facilities are competitive sources of power. Balancing one against the other is often discussed by engineers who are prejudiced in favor of hydro or of steam. It is the object of this paper to point out that each proposed hydro development should not be measured against an equivalent steam installation as a sole source of power, but that it is necessary to forecast the characteristics of the particular system in which additional capacity is required and to determine for the particular conditions whether the addition of steam or hydro will give the lowest total cost of power supply for the system.

Joel D. Justin

THE downward trend of steam-plant operating costs has often been cited as a reason for favoring steam as a source of power. During the past 20 years there has been a remarkable increase in steam-plant efficiencies which seem impossible or unlikely to be duplicated, although it may still be unsafe to predict what the future may offer. It is interesting to refer to a chart that was presented in the July 4, 1925, number of *The Electrical World* and taken from a paper presented before a meeting of the A.I.E.E. The footnote to this graph states: "This curve . . . represents the weighted average in connectiou with the performances plotted for 22 stations. . . . The dotted extension of the curve is our estimate as to the future possibilities in the way of improved performance for a station designed to operate on the straight steam cycle with a single stage of reheating."

Points on this graph are as follows: 1913, 22,500 Btu per kwhr; 1916 to 1921, 19,500 Btu. Then appears the sharp downward break which reached 14,500 Btu by 1925. The "dotted extension" from 1925 straightens out until in 1929 it reaches 13,000 Btu and has been extended flat at 13,000 Btu as far as 1932. In 1931, however, at least one plant with a single stage of reheat averaged 12,000 Btu for the year and was operating between 200 and 300 Btu less than 12,000 for six months. While predictions of future steam efficiency seem extremely unreliable, it is safe to say that the best which can be foreseen is approximately 10,000 Btu when utilizing steam at 2500 lb and 1000 F and 8500 Btu with the mercury cycle.

In considering steam-generated power costs considerable speculation is necessary regarding fuel costs. At the present time coal is probably being sold at prices that do not provide an adequate return on the coal-mining investment and may even yield little more than the mining cost. While it would seem reasonable to assume that this condition will not persist, the competition of other fuels will tend to hold coal prices down.

Component Parts of Steam-Operating Costs

When estimating the cost of blocks of power under system-load curves from various existing or contemplated steam plants, it is necessary to break these costs into their component parts. The commonly used division is between the fixed charges and the operating costs, considering the fixed charges as a cost per kw of capacity and the operating expenses as costs per kwhr. A very much more accurate forecast can be prepared if the operating expenses are also divided into their component parts, which might be termed "fixed component," "peak prepared," and "increment cost of energy." There are certain annual costs which accrue in a steam plant regardless of the peak load carried or the amount of energy generated. This is termed the "fixed component" and includes portions of the superintendence, labor, supplies and expenses, maintenance, and a small amount of fuel. The second component is caused by having the station prepared to supply a given load. Included in this item, besides superintendence, labor, and maintenance, must be the fuel necessary to keep the required generating capacity turning over at no-load output. This expense varies with the kw load that the plant prepares to carry. If the first two components have been properly allocated, the variable cost is directly proportional to the amount of energy generated, and therefore can be reduced to a cost per kwhr.

For preliminary economic studies, such as those discussed herein, it is feasible to use only two factors (annual capacity cost per kw and energy cost per kwhr), the first as the total of the first three items mentioned, and the second the variable. It should be emphasized that in using two factors a portion of the

The same year he entered the employ of B. F. Sturtevant Co., Hyde Park, Mass.; later he was with Stone & Webster, Boston, Mass. He served in the Navy during the war. He was with the United Gas Improvement Company from 1919 until 1931. Mr. Irwin was Chairman of the Philadelphia Local Section, A.S.M.E., 1931.

[2] Hydroelectric Engineer, United Gas Improvement Company. Mr. Justin was graduated from the College of Civil Engineering, Cornell University, in 1906. In recent years he has devoted much time to studies and investigations relating to the economics of power supply for various power companies. For the past 18 years he has been connected with the investigation, design, and construction of hydroelectric projects. He is co-author of "Hydro Electric Handbook" (Creager and Justin) and author of "Earth Dam Projects," and various articles and papers.

Contributed by the Power Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

operating expense is treated as constant per kw and added to the fixed charges in place of treating only the fixed charges as constant and all of the operating expenses as varying with output, and also that peak prepared for is assumed equal to installed capacity.

In Table 1 are given the cost elements of a few typical plants.

The capital cost of steam plants varies over 100 per cent. Some of the factors causing the variation are the price of materials, the foundation conditions, local building restrictions, size of installation, number of units, and the amount of advance expenditure made for future extensions. The size of the plants also has a marked effect in reducing the fixed operating cost per kw.

For a new plant to replace an old one on the load, the cost of operating plus the cost of fixed charges must be less than the operating cost of the old plant. From Table 1, therefore, the cost developed from columns 6 and 7 must be less than the cost derived from column 5 plus column 7. With relatively high load factors or long hours' use, the low increment cost of the new plant makes this replacement of new for old plants economical, but for low load factors it is often less expensive to continue to operate high operating cost plants.

TABLE 1

1	2	3	4	5	6*	7
Plant	Date built	Fuel cost, cents per million Btu	Capacity, kw	Fixed operating per kw	Annual capacity cost per kw	Variable operating, mills per kw-hr
A	1930	13.5	120,000	2.10	14.10	1.73
B	1926	15.35	130,000	4.50	16.50	2.42
C	1920–1926	18.05	135,000	4.73	16.73	2.63
D	1924–1927	17.85	215,000	4.52	16.52	3.32
E	1923	9.54	27,000	11.42	23.42	3.46
F	1917–1921	17.75	160,000	11.80	23.80	3.27
G	1911–1915	9.54	65,000	11.46	23.46	4.10
H	1917	16.05	20,000	8.15	20.15	4.60
I	1905	17.85	17,000	13.50	25.50	6.70

* The sum of column 5 and the fixed charges assumed 12 per cent on $100 per kw in every case.

Thus, the total annual cost of Plant A of Table 1 is less than the annual operating cost for Plants D, E, F, G, H, and I at 30 per cent load factor, but at 10 per cent load factor only less than Plant I. Likewise, Plant B is less than H and I at 30 per cent, but only less than I at 10 per cent load factor.

The fixed charges referred to are made up of the return on the investment, an amount set aside for replacement fund, insurance, and taxes. The first item varies from 6 to 8 per cent of the capital invested. The depreciation is variously estimated by different engineers from 3 per cent to 4 per cent on steam plants; insurance payments generally average one-half of 1 per cent. The taxes on real estate and personal property rarely exceed 1 per cent. For studies of this kind, these are the only taxes that need be considered. Some states levy gross-receipts taxes in lieu of personal-property taxes; and for general corporate purposes, these, together with income taxes, are often apportioned as percentage of investment and are included in the fixed charges. It is not correct to include such taxes in an economic study, because they are dependent on output or profit and bear no relation to investment.

In Table 1, carrying charges have been assumed as 7 per cent return on investment, $3^1/_2$ per cent for depreciation, 1 per cent for taxes, and $^1/_2$ per cent for insurance, a total of 12 per cent.

Changing Economic Function of the Hydro Plant

In the past many hydro plants were constructed as the sole source of power supply for a community or section. Under such conditions, it is necessary that the minimum flow of the river should be sufficient at time of maximum power demand to give all the power that is required to meet the load.[3] Except where seasonal regulation through natural or artificial storage was available, there resulted a tremendous wastage of water over the dams during the greater part of the year. Utilization factors of as low as 35 per cent were not uncommon in such plants. Utilization factor as used in this connection means the ratio of the annual amount of energy obtained from the plant to the annual energy that might have been obtained from the same plant with the same stream flow if the connected load had been capable of absorbing all of it.

In such plants the investment in lands, dams, and riparian rights was necessarily relatively high compared to the investment in power house and equipment because of the relatively small installation. As a result the total cost of the development was high per unit of installed capacity.

Except in the case of certain favored sections where development costs are low and natural or artificial storage is readily available, or in sections where fuel is extremely high in cost, it is no longer economic to install hydro plants as a sole source of power supply.

Most companies having hydro plants as the only source of power supply based their installation on flows somewhat higher than the minimum, because the cost of the additional installation was very low. During the greater part of the year, such companies had available large amounts of secondary power which they could not utilize on a normal public-utility load curve. A part of this secondary power was salable on a when, as, and if available basis to industries which could afford to shut down a part of their operations during periods of low water. With the development of long-distance transmission, these companies extended their transmission lines to interconnect with other companies served exclusively by steam plants, thus being able to sell their surplus hydro energy during periods of plentiful stream flow and receive in return steam-generated electric energy during periods of low stream flow.

Through a continuing process of integration, the consolidated companies now contain groups of steam and hydro plants. It has thus come about that steam and hydro, which used to be considered as highly competitive alternatives, have become complementary sources of power supply.

Firm Hydro Capacity

In any large system the power supply of which consists of both steam and hydro plants, it is always feasible and generally quite economical to supply the requirements of the increasing load through the construction of additional steam capacity. If, however, the system includes available hydro sites, it is necessary to conduct quite an extensive economic study in order to determine whether the additional load can be most economically supplied by a new steam plant or by a new hydro plant.

As steam is the yardstick by which the economic advisability of hydro must be measured, about the first things which must be determined with regard to any hydro project (after its physical features have been investigated) is whether the proposed hydro capacity can do the same work that an alternative steam plant might perform on the existing load curve. If the hydro plant can do this, its capacity is said to be "firm." The firm capacity of a hydro plant may be defined as that portion of its total capacity which can perform the same in that portion of the load curve assigned to it which alternative steam capacity could perform.

The minimum 24-hour power available at the site is sometimes incorrectly spoken of as the firm capacity. This can be true only in the case where there is absolutely no pondage. With

[3] An exception to this rule is furnished by such industries as the paper mills and aluminum industry, which can afford to utilize a certain amount of seasonal power.

large pondage and favorable load conditions, the firm capacity of a hydro plant may be many times the minimum 24-hour power available. In the case of some existing plants which are parts of large systems and are possessed of ample pondage, the firm power is ten or more times the minimum 24-hour power available.

The concept of firm power will be plain by reference to Fig. 1, which is the load curve of a large power system for the maximum-demand and maximum-energy week. In the system under consideration, the maximum demand always occurs in December. The hydro project under consideration would have a large pond of ample capacity to provide weekly regulation with an insignificant drawdown. It is apparent from Fig. 1 that the upper part of the load curve contains relatively little energy. If we measure down from the peak of the curve a distance equal to a proposed capacity for the hydro plant, the energy in that portion of the curve above a horizontal line drawn through this point may be determined by planimetering or otherwise. If the energy as determined is equal to or less than the amount of energy obtainable from the stream flow in a week of minimum December flow, then the proposed capacity will all be firm capacity, because it can perform the same function on the load curve as alternative steam capacity.

The foregoing is the most simple curve which assumes that there are no other hydro plants in the system. If other hydro plants are already in the system, the cumulative total of their firm capacity must first be laid off, measuring down from the peak of the load. The firm capacity of a proposed additional plant will then be indicated by the width of the horizontal band immediately below, which contains an amount of energy just equivalent to energy available at the proposed new hydro plant during a week of minimum December flow.

If the characteristics of the load are not already well known, it may be necessary also to study load curves for many other weeks of the year, because, although the load at other times of the year is less, the load factor may be higher and the stream flow less.

The determination of firm capacity, utilizing the actual load curves and the cut-and-try methods indicated, is very laborious, and consequently the work is greatly abbreviated by the use of mathematical curves.

Peak Percentage Curves

To prepare a mathematical curve to be used in determining firm capacities, it is first necessary to plot a load-duration curve for the period under consideration. This is done by arranging the loads hour by hour in order of magnitude and plotting, using loads as ordinates and time as abscissas. Areas underneath the curve thus represent energy. In the most convenient form of load-duration curve, per cent of total load is plotted as ordinates and per cent of time as abscissas. Such a curve may then be applied to many different years (assuming no change in shape of load curve). A load-duration curve is shown in Fig. 2.

The peak-percentage curve is obtained from the load-duration curve as follows. Beginning at the top of the curve, cumulative areas are determined by increments by planimetering or otherwise. From this data, a peak-percentage curve, such as that

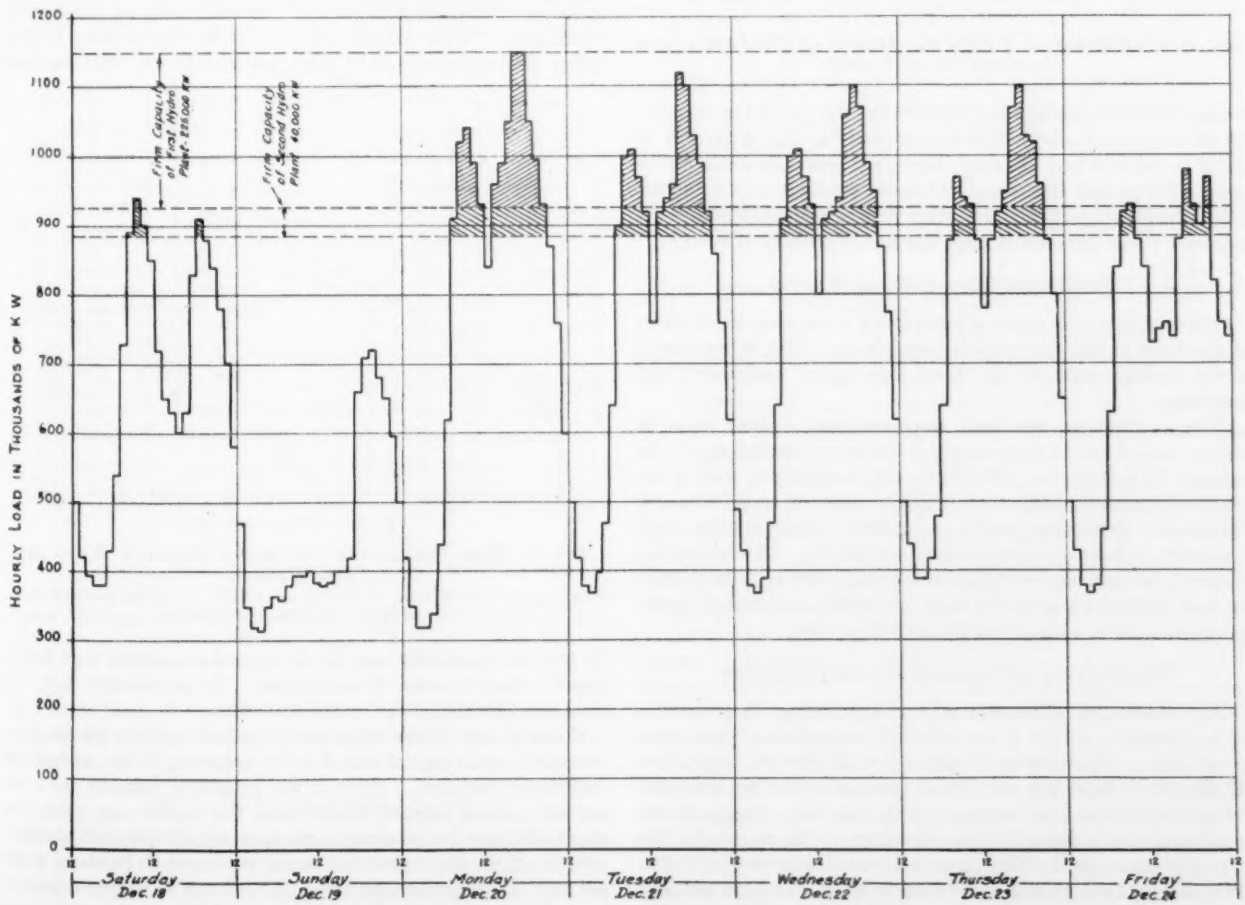

Fig. 1 Load Curve for Peak-Load Week in December, 1926, Large Power System
(Kwhr for week, 122,000,000; hydro kwhr, 5,860,000.)

shown in Fig. 3, is obtained. (Figs. 1, 2, and 3 are all for different power systems.)

In order to illustrate the use of the curve in as simple a manner as possible, it will be assumed that at the present time there is no hydro capacity in the system, but that the company is contemplating the development of a site to be completed for the 1934 load.

At the proposed site, which has ample pondage, there will be available in a week of minimum December stream flow, 900,000 kwhr, which from the table in Fig. 3 is 5.4 per cent of the total energy for the week. Using the curve, this corresponds to 24.5 per cent of the load. In other words, in the top 24.5 per cent of the load, there is only 5.4 per cent of the total energy. As the

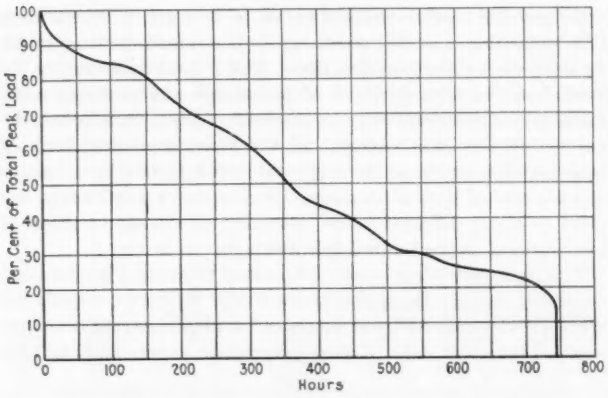

FIG. 2 LOAD-DURATION CURVE FOR MONTH OF DECEMBER OF A REGIONAL POWER SYSTEM

total estimated load in 1934 is 187,000 kw, the amount of capacity which may be installed and be firm capacity in 1934 is 187,000 × 0.245 = 46,000 kw. It may, however, prove desirable to so design the project that some additional capacity may be added at a later date, particularly if river flow is such that additional capacity would generate a large amount of additional energy.

INCREMENT COST OF HYDRO PLANTS

The capital cost of hydro plants per kw varies over much wider limits than is the case with steam plants. This is because a much smaller part of the total cost is in equipment and buildings.

For any given site and head, the investment in land, riparian rights, and dams is very nearly a constant, regardless of the amount of installation. However, the incremental cost of installation, meaning those costs which roughly are proportional to installation, consisting mainly of building, intake conduit, and equipment, varies within much narrower limits. An examination of cost data for a number of plants varying in capacity from 3000 to over 200,000 kw indicates that the incremental cost of hydro plants in general varies from $55 to $70 per kw.

SIGNIFICANCE OF INCREMENTAL COST OF HYDRO

The importance of incremental cost as affecting the economics of hydroelectric plants is not generally recognized. Thus, at a given site, a plant having a capacity of 20,000 kw might cost $7,500,000, or $375 per kw. In all probability the requirements for additional power and energy could be met more cheaply by the construction of a steam plant. However, at the same site, the capacity might be doubled at an additional cost of $1,000,000. The cost per kw installed would then be $212, and quite possibly the project might prove economic at such time as all the capacity became firm capacity on the load curve.

EFFECT OF INCREMENT CAPITAL COST ON ECONOMIC FUNCTIONS OF HYDRO PLANTS

The effect of the unusually low increment capital cost of hydro installation in determining the advisable use to be made of a hydro project may be fully understood by a study of Fig. 5. Curve *A* in this figure gives the total cost of energy per kwhr for a modern highly efficient steam plant.

Curve *C* gives the total capital cost per kw of installation for a hydro plant if installed for various annual capacity factors. The plant is a fairly typical hydro plant on a fairly typical American river, having an average annual runoff of about 1.5 cfs per square mile and a range of flow varying from a weekly minimum of 0.15 cfs per square mile up to over 28 cfs per square mile. Thus the larger the installation, the greater the amount of energy turned out by the plant during any given year. It should, however, be remembered that the annual capacity factor of a hydro plant decreases with increased installation. The plant has ample pondage for weekly regulation, which is a prime requisite for any hydro project if all its capacity above that required for minimum stream flow is ever to become firm on the load curve.

In order to arrive at the capital cost per kw of installation for various capacity factors, an actual operating modern plant on this river was selected. The actual total costs were segregated in items which would be the same regardless of installation, such as lands, water rights, dams, railroad changes, and highway, and the items which vary with the amount of installation, such as power house, equipment, turbines, and transmission. This latter group constitutes the increment cost of installation and was found to be approximately $70 per kw. Starting with an installation which gives 100 per cent capacity factor (or that required to just utilize the minimum weekly flow), the installation was increased

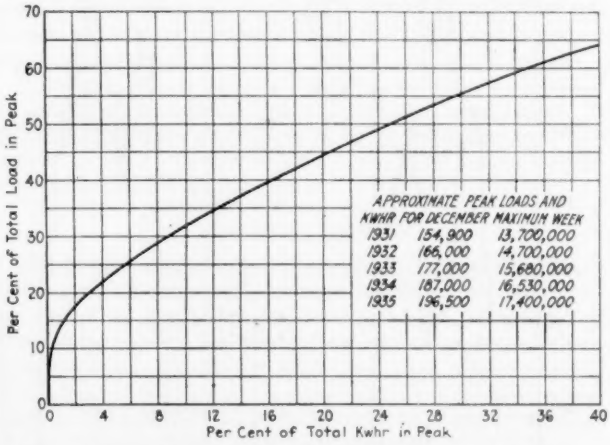

FIG. 3 PEAK PERCENTAGE CURVE FOR MAXIMUM WEEK OF DECEMBER

(Showing per cent of total kwhr in peak of load of regional power system Load factor of curve, 55 per cent.)

by increments and the capacity factor and cumulative cost determined for each increase in installation. To get the unit cost, the total was divided by the total installation.

Curve *C* then shows for a fairly typical case the tremendous variation in unit capital cost of hydro according to the amount of installation installed. Thus, if the project is planned on a 90 per cent annual capacity-factor basis, the capital cost would be about $580 per kw, whereas if planned on a 20 per cent annual-capacity basis, the capital cost would (by curve *C*) be about $100 per kw. It should here be noted that in order to be firm capacity on such a low capacity-factor basis, it would probably be necessary for the connected load to be three or four times the installed

hydro capacity, and thus the load would absorb all hydro energy generated. The curves are applicable only for the case where all hydro capacity installed would be firm capacity on the load curve. In fact, it seldom pays to consider hydro installations on a low capacity-factor basis unless all the capacity is firm.

In order to obtain curve *B*, it was necessary to obtain the amount of energy available for the installation required to give the various capacity factors. For this purpose, flow and power duration curves of the fairly typical stream selected were utilized.

Total annual charges on hydro were taken at 10 per cent of capital cost, and to get the total cost of energy, the annual cost per kw was divided by the energy produced per kw of capacity. Curve *B* shows the typically very high cost of hydro energy as compared to steam at high capacity factors and its relatively low cost compared to steam on low capacity factors. At a 70 per cent capacity factor, it will be noted that in the given case the costs of steam and hydro power are equal.

While there are many situations in which, if curves similar to those shown were plotted, the results obtained would be quite different from those shown, nevertheless it is believed that the curves are fairly typical for many situations.

Most emphatically the curves should not be interpreted as showing that either steam or hydro is the cheaper source of power supply. The only thing that ever makes it feasible to install a hydro project on a relatively low annual capacity-factor basis is the existence of a connected load several times the hydro capacity served largely by steam plants.

Under more or less exceptional conditions, hydro plants having very high annual capacity factors are economically feasible. Niagara Falls is a frequently cited example of this. There are

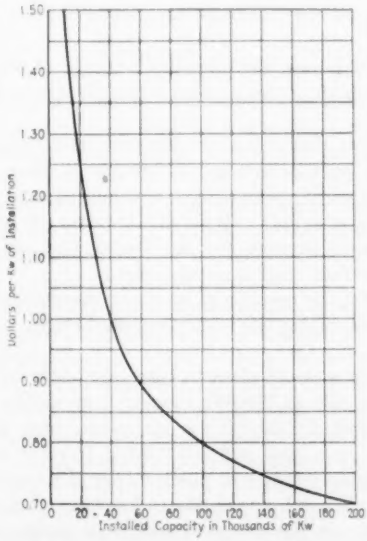

FIG. 4 OPERATION PLUS MAINTENANCE COSTS AT TYPICAL MODERN HYDRO PLANTS
(Based on a study of records of over 50 plants.)

also many projects on rivers which are well regulated by natural or artificial storage where costs on high capacity factors are relatively low.

ANNUAL COSTS OF HYDRO PLANTS

There is a wide variation in the practices of various companies with regard to the fixed charges set up for economic studies. The actual rate utilized is not of as great importance as it is that the fixed charges for both steam and hydro plants should be on a truly comparable basis.

Cost of money should be the same in either case, but the total fixed charges on hydro should almost always be less for hydro than for steam. Depreciation should be much less for hydro than for steam, because a very high percentage of the total investment is in items that are not depreciable or that are subject to a very slight depreciation, such as lands, riparian rights, and structures of earth and concrete.

In any particular case the annual depreciation should be

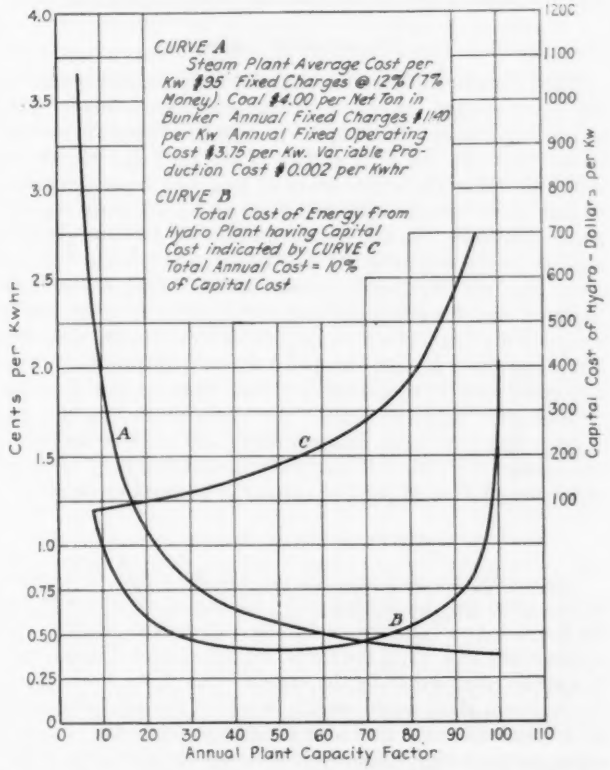

FIG. 5 TOTAL COST OF ENERGY AT VARIOUS CAPACITY FACTORS AT STEAM AND HYDRO PLANTS

computed item by item by the sinking-fund method. The overall annual rate so computed will in general vary from 1.5 per cent for projects where most of the investment is in the power plant, down to 0.5 per cent for a project where a large proportion of the nvestment is in water rights, land, earth dams, and tunnels. In making preliminary studies it is usually satisfactory to select a rate of depreciation between these two limits, based on well-informed judgment. For illustrative purposes only, 1 per cent per year on the total cost of the project has been selected as representing depreciation on an average hydro plant and being fairly comparable with the $3^1/_2$ per cent used on steam plants herein.

The cost of taxes and insurance is generally less for hydro plants. The relative investment in items on which insurance is issued is much less, and taxes are usually at a lower rate because hydro plants are usually located in rural sections remote from the centers of population.

Some small hydro plants have very high annual costs for operation and maintenance. Some of them with capacities of a few thousand kw or less have costs for operation and maintenance up to $6 per kw per year. However, with the present availability of remote control and automatic apparatus, there is probably no need for such costs exceeding about $2 per kw per year. Operation and maintenance costs at hydro plants should vary roughly with capacity, size, and number of units. Based on a study of

the cost records of a large number of operating plants, Fig. 4 shows approximate operation and maintenance costs for typical modern hydro plants.

Based on the foregoing data, the annual costs for hydro plants have been taken as follows for the illustrative purposes of this paper: Money 7 per cent; depreciation, 1 per cent; taxes and insurance, 1 per cent—total fixed charges, 9 per cent.

To obtain total annual cost, there should be added the annual cost of operation and maintenance as obtained from Fig. 4.

Transmission Costs

When considering the advisability of adding a hydro plant to any power system, the cost of transmission is sometimes of paramount importance. Some hydro projects are located in sections remote from the center of gravity of the load, and require for their utilization the construction of long and expensive transmission lines. On the other hand, in the case of some regional power companies, the additional transmission facilities required must be just as extensive if a new steam plant is built. In any given case the transmission requirements should be carefully analyzed, and the additional cost of transmission which will be necessary if a hydro plant is built, but which will not be necessary if a steam plant is built, should be carefully determined. This differential cost of transmission is sometimes spoken of as the "transmission liability" against the hydro plant. In the case of large hydro projects requiring 60 to 150 miles of additional transmission for their sole use, the "transmission liability" may vary from $2.50 to $7 per kw per year of installed capacity.

Value of Hydro Energy

It is usually assumed that the value of the output of a hydroelectric plant may be determined by the annual capacity cost and the increment cost of energy at an alternative steam plant. This is necessarily true only if the annual capacity factor of the alternative steam plant would be the same as that of the hydro plant. A new steam plant would usually be one of the most efficient in the system and would have a very high capacity factor. In such a case, excess energy which would annually be turned out, multiplied by the difference in increment steam cost between the proposed new plant and existing steam plants, should be subtracted from the total value of the hydro energy.

It should, however, be recognized that this is only a temporary liability of the hydro plant. As new steam plants are added, the capacity factor of the alternative steam plant will decrease, until it will soon be no greater than that of the hydro plant. For this reason it is often sufficient to consider this liability as counterbalanced by certain hydro advantages which may not always be readily evaluated in dollars and cents, such as peak-load service and reserve capacity.

Set-Up for a Typical Hydro Project

A power system requires additional capacity of about 50,000 kw in order to be able to serve the anticipated load of 1934. A suitable hydro site is available, and the company desires to determine whether it will be more economical to install a hydro plant or a steam plant for the next step in the development of their power-supply resources. Thorough field investigations, office studies, and estimates of cost for the hydro project have been made. The pondage at the site has been determined as ample for weekly regulation with only slight drawdown. By methods already outlined, it has been determined that 50,000 kw of capacity may be installed at the site and be firm capacity on the load curve of 1934. The energy available during a peak-load week coincident with minimum stream flow has been determined as 2,000,000 kwhr. Accordingly, during such a week, the plant would be operating on a load factor of 23.8 per cent. The output of the plant during the average year has been determined as 240,000,000 kwhr, giving an annual capacity factor of 55 per cent. The characteristics of the project are evidently such that although only 50,000 kw capacity would be firm in 1934, a much larger installation will prove advisable at some time in the future, and accordingly provision has been made in the design for readily extending the power house and increasing the capacity. The total capital cost of the project with an initial installation of 50,000 kw has been estimated as $8,750,000.

In accordance with the principles outlined, a careful study has been made of the transmission liability of the project, which has been determined as $3.72 per kw per year of installed capacity.

The alternative steam plant would be located at the load center, and its annual cost has been determined as $15 per kw per year, plus 2 mills per kwhr for energy.

The transmission losses are 6 per cent in capacity at time of full load, and average loss of energy would be 4 per cent. The delivered power would be $0.94 \times 50{,}000 = 47{,}000$ kw, and the delivered energy would be $0.96 \times 240{,}000{,}000 = 230{,}400{,}000$ kwhr. Based on this data, a set-up for the project may be made as follows:

1	Annual value of hydro power and energy delivered in an average year (based on costs at alternative steam plant):	
	47,000 kw delivered at $15	$705,000
	230,400,000 kwhr delivered at 2 mills	460,800
	Total annual value of hydro output delivered	$1,165,800
2	Annual total cost of hydro power delivered:	
	Fixed charges on hydro development, 9 per cent on $8,750,000	$787,500
	Operation and maintenance of plant (Fig. 4) 0.95 × 50,000	47,500
	Total annual cost of transmission (as above)	186,000
	Total annual cost of hydro power delivered	$1,021,000

Hence in this case the annual advantage of the hydro plant over the alternative steam plant is $1,165,800 — $1,021,000 = $144,800.

It is believed that this method is preferable to any attempt to show return on the investment, because it shows directly the effect on the earnings statement of adopting one of alternative sources of power supply. It should, however, be recognized that the investment required for the hydro alternative is usually much greater than that of a steam plant.

Accordingly, the reaction of an executive charged with the responsibility of raising the money required might be expressed as follows:

"If we built a steam plant to take care of the increasing load, it will cost us only $4,700,000, whereas if we build a hydro plant, we must spend $8,750,000 for the plant, plus $1,550,000 for transmission, or a total of $10,300,000. In other words, we will have to spend over twice as much money if we adopt the hydro alternative. What I should like to know is, what return are we going to make on this proposed additional investment?"

This question may be answered, with the aid of the data already given, as follows:

ANNUAL COST OF DELIVERED HYDRO POWER EXCLUDING INTEREST ON EXCESS INVESTMENT IN HYDRO

Depreciation, taxes and insurance on hydro development, 2 per cent on $8,750,000	$175,000
Operation and maintenance of hydro plant	47,500
Operation, maintenance, depreciation, taxes and insurance on transmission facilities, 5 per cent on $1,550,000	77,500
Interest charges on cost of alternative steam plant, 7 per cent on $4,700,000	329,000
Total annual cost of delivered hydro, exclusive of interest on excess investment of $5,600,000 ($10,300,000 — $4,700,000)	$629,000
Annual sum available for return on excess investment in hydro, $1,165,800 — $629,000	536,800

Return on excess investment in hydro = 536,800 ÷ 5,600,000 = 9.6 per cent.

Economic Balance Between Steam and Hydro Capacity

The hydro ratio is sometimes used to express the relationship between the hydro capacity in a given system and the annual peak load of the system. The "economic hydro ratio" may be defined as that ratio of hydro installation to peak load which for the given company gives the minimum annual cost of power supply. The economic balance between steam and hydro capacity for a given system at any given time is largely dependent on the following factors: shape and size of load curve, availability of suitable hydro sites, additional transmission facilities required for hydro ("transmission liability"), runoff and its seasonal distribution, availability and cost of storage, cost of fuel, and availability of condensing water. Clearly the "economic hydro ratio" may vary from zero in sections where hydro sites are extremely expensive and fuel cheap up to 100 per cent for sections where fuel is extremely expensive and suitable hydro sites with well-regulated stream flow abundant.

In some locations where fuel is cheap, but where favorable hydro sites are available, the economic hydro ratio has been shown to be from 25 to 40 per cent. In certain other regions where fuel is somewhat more costly, but where very favorable hydro sites are available with relatively cheap storage, the economic hydro ratio is from 60 to 70 per cent. In certain sections of Canada, the ratio is even higher.

A further decrease in the cost of steam-generated power will to some extent affect the economic hydro ratio, but will have more effect in changing the function of the new hydro plants constructed; that is, decreases in cost of steam will dictate the construction of hydro plants designed to operate on lower annual-capacity factors.

Discussion

W. F. Uhl.[4] This paper is a brief but comprehensive exposition of the economic relation between hydro and steam power in a large interconnected public-utility system.

There are still instances, of course, where hydro and steam power are truly competitive, as in the case of industrials producing their own power and some of the smaller public utilities. In the case of industrials, the problem is often complicated on account of the demand for heat for various purposes.

Except for a few companies located in the Rocky Mountain states and at Niagara Falls, all of which operate with high load factors, dependence on hydro power alone has not been found to be economical. The earliest industrial water-power developments of importance, such as those at Lawrence, Lowell, Holyoke, etc., recognized the economic importance of development much beyond the minimum stream flow, and arranged to sell surplus mill powers which were supplemented by steam plants installed by the industries purchasing such surplus water. Such surplus water has become less valuable as steam-power generation has become more efficient.

The contrary is the case with large interconnected public-utility systems operating with comparatively low load factors, if storage and pondage can be developed at reasonable cost, and this has been pointed out by the authors, who have shown simple methods for the determination of the necessary economic facts.

It is comparatively simple to make an economic study of the relations between hydro and steam power for any assumed conditions of load, but it must be recognized that since conditions which may exist in the future are always dealt with in such studies, the results should not be taken too seriously. Much time and effort are often wasted in making such studies with too great precision.

Perhaps our public-utility systems will not change so rapidly in the future as they have in recent years, and calculated comparisons may then hold true for longer periods. In some cases it has proved helpful to make two sets of assumptions covering future conditions as to load, interconnected plants, etc., thus obtaining comparisons within certain rational limits.

The authors have defined certain terms that are often misused, such as "increment cost of energy," "firm capacity," etc. It is of the utmost importance that the meaning of such terms be properly understood, as much confusion has resulted from the careless use of such terms in the past.

The authors have pointed out that there is a wide variation in the practices of various companies with regard to the fixed charges set up for economic studies. This is true, and it is believed that in many cases this is the result of a misunderstanding of the facts. The cost of money and the rate of return have been badly confused. Since the fixed charges on hydro plants are the only annual charges of importance, and since the interest charges (cost of money) form a large percentage of such charges, it becomes very essential that this cost be quite definitely established when the annual cost of hydro and steam power is compared. The cost of power (the product that a public utility sells) has nothing to do with the rate of return on the value of all the property, tangible and intangible, that the utility uses in its business, and which rate of return includes interest and profit.

The average cost of money, interest and dividends, has been found to amount to about 6 per cent on their assets for a number of public utilities recently coming under our observation.

Our examination of the actual cost of taxes and insurance on hydro plants and steam plants owned by the same company, covering a period of 11 years, showed that the average taxes for this period amounted to 0.81 per cent for the hydro and 1.23 per cent for the steam plants; the insurance amounted to 0.0307 per cent for the hydro and 0.264 per cent for the steam plants. In both cases the percentages are on the total actual investment in plants, including all overheads.

The relative depreciation between hydro and steam plants is often a matter of controversy. Recently a hydro plant built in 1900 was carefully examined, and it was decided to install one new modern vertical unit in place of one of the old horizontal double-runner units. Three of the old units are still in operation and in fair mechanical and electrical condition. The same penstock that supplied the old unit was utilized for the new unit. This penstock was thoroughly examined and found to be in substantially perfect condition. No important changes were made in the power house and none whatever on the intake, dam, tailrace, etc. These structures are all in excellent condition, and very little has ever been spent on them for maintenance and repairs. What rate of depreciation should have been used to calculate the yearly cost of power from this plant?

Where are the steam plants built in 1900, and what rate of depreciation (including obsolescence) is applicable to such plants?

The situation as described for this particular hydro plant is probably unusual for one built as long ago as 1900 or thereabout, but it certainly should not be unusual for plants of any importance built more recently, if designed and the construction supervised by competent engineers.

A hydro plant does not always have to carry a transmission liability. A case recently came to our attention where a large company had a hydro development near the outskirts of its system, where it supplies most of the local load. In determining the value of power lost by diversion of water for municipal use, this plant was credited with savings of both transmission investment and transmission losses. Voltage regulation is also frequently

[4] Hydraulic Engineer, Chas. T. Main, Inc., Boston, Mass. Mem. A.S.M.E.

improved by even small hydro plants near the ends of transmission or distribution feeders.

Our experience seems to indicate that the apparent saving in operating cost of hydro plants by the installation of automatic equipment is generally more than wiped out by the additional fixed and maintenance charges on the equipment. If the plant is of any importance, a watchman is often required in any case and this also should be taken into account. Partially automatic plants will often indicate a saving where a fully automatic plant would not make such a showing.

GEO. A. ORROK.[5] This paper is a welcome addition to the Society proceedings, since it covers the newer ideas regarding economic balance between steam and hydro capacity and the economic hydro ratio as well as certain features of increment cost that have been perhaps too little emphasized in the past. These studies follow the earlier peak-load–base-load studies of steam-plant combinations and make very clear the values of the addition of pondage and storage to the hydro plant in its connection with a steam-hydroelectric supply system. Many of us who have been accustomed to paying $2^1/_2$ per cent for taxes may not feel easy at the suggestion that taxes rarely exceed 1 per cent when they concern property values; but this is a minor matter, and the argument in the paper has been carefully thought out and fully explained.

It is a question whether the Hopkinson method of calculating the kilowatt-hour cost of steam plants gives any better results than the more ordinary methods that have been used by Professor Christie and myself, and it is my personal opinion that a reserve should be taken into account in connection with the steam costs, particularly in important installations. I note that the differences in the steam cost between the figures in this paper and my paper at Pittsburgh last November are of the order of tenths or hundredths of a mill when the reserve is taken out of consideration.

The authors are to be congratulated on their presentation of a difficult subject.

A. G. CHRISTIE.[6] This paper is timely and will be of especial interest to engineers. The extended interconnection of power systems in which there are frequently available certain capacities of water power that are now or may be developed has increased the importance of the economic balance between steam and hydro. As the authors emphasize, these two supplies are no longer competitive, but are now complementary.

In the second paragraph the authors discuss the trend of steam-plant performance and indicate 10,000 Btu per kwhr with 2500 lb and 1000 F. This figure checks closely with some computations on plant efficiency made by the writer and appears to be about the best that can be hoped for with present processes of steam generation.

In connection with fixed charges on the steam plant the authors use 3 to 4 per cent as a depreciation allowance, which, on a straight-line basis, would presume an average life of 25 to 33 years for the plant and equipment. This life allowance appears to be too great when full consideration is taken of obsolescence and supersession. It is a fair presumption that gains in economy are still possible in steam-station equipment, and these will lead to supersession of the older units, particularly if fuel prices tend to increase to any great extent above current levels. A higher allowance for depreciation would seem justifiable.

The discussion of firm hydro capacity might be amplified by considering the case where the hydro plant operates as a base-load plant during stages of high water and the steam station as a base-load plant during low water when ample pondage is provided at the hydro plant to store over the 24 hours. These changes in operating conditions involve considerable modifications in load dispatching. Many systems operate successfully on this method of loading.

The authors say nothing about the economics of pumped storage, although provision for such has been made in one or more recent plants of large size.

Fig. 3 shows a curve that, together with the load-duration curve, should receive more study by engineers. The writer has emphasized for years the relatively small output represented by the upper portion of the system s installed capacity. For instance, the upper 20 per cent of the total system capacity generates only 3 per cent of the total output in kwhr. This warrants the installation of plants of minimum total production cost of energy for such peak-load service.

Ample pondage is assuming an important place in the consideration of hydro developments. As the authors point out, the increment cost of added capacity to a given plant is relatively small. On the other hand, if pondage is sufficient, this added capacity can carry portions of the peak load at a lower cost than equivalent steam plant.

The figures in the comparisons under the heading, "Set-Up for a Typical Hydro Project," show a rational engineering analysis of the problem. All hydro-steam system problems are not so susceptible of easy solution. In one case, the problem of evaluating secondary hydro power available only during high water that occurred in summer time presented many difficulties. The steam station at the end of a transmission line 175 miles long had to be maintained at full capacity to carry the winter peak loads should outage occur. This placed a small value on the secondary hydro power. Another problem in the same system was to determine the proper place of steam-generated power if used as base load in the winter months and to assess a proper valuation for such power. In this particular system the hydro plant and the steam plant were owned by different interests. Problems involving costs were therefore approached from different viewpoints.

In Ontario and Quebec, reliance has been placed on hydro power alone due to the fact that foreign coal must be imported into these areas. If this restriction could be removed by ample supplies of Canadian or British coals, some interesting problems of economic balances between steam and hydro power would develop. The result would probably lead to the development of steam stations in the larger centers, although Diesel plants need consideration in certain cases.

W. P. CREAGER.[7] The authors give a rather lengthy computation to indicate the percentage return on the excess investment in hydro. Instead of this means of determining it, I would suggest a more abbreviated method.

The total return on the excess hydro investment is equal to the annual saving by the hydro plus the interest charges on the excess investment. The percentage return may then be computed as follows:

$$\text{Percentage return} = \frac{144{,}800}{5{,}600{,}000} + 7.00 = 9.6$$

R. L. THOMAS.[8] A perennial question on which engineers seem to disagree within an astonishingly wide range and which the authors handle with much discrimination is the rate or rates of fixed charges to be applied to investment in steam and hydro

generating plants. In 1929 Mr. W. W. Tefft[9] used 18 per cent for steam and 10 per cent for hydro. In an A.I.E.E. paper[10] presented at Cleveland in June, 1932, Mr. R. E. Dillon said of steam plants that "the fixed charges per kilowatt of new capacity at the present time would be $17." Messrs. Irwin and Justin use 12 per cent or $12 per kilowatt for steam (exclusive of the fixed operating cost) and 9 per cent for hydro. They call attention to the often neglected fact that "the actual rate utilized is not of as great importance as it is that the fixed charges for both steam and hydro plants should be on a truly comparable basis."

Nevertheless, the absolute values, regardless of the differential, do have considerable influence on the result of the authors' method of comparison. Referring to their numerical example showing an advantage of $144,800 in favor of hydro, this advantage would be increased if both rates of fixed charges were decreased alike, and it would be decreased if the rates of fixed charges were increased. If both rates were increased sufficiently, the credit to hydro would become a debit. It follows that the omission of an item of fixed charges, such as a tax, does affect the result, even if it is the same in per cent for both hydro and steam.

The authors' treatment, or rather their disregard, of income and gross receipts taxes in computing fixed charges raises some interesting and puzzling questions. Under the heading, "Component Parts of Steam-Operating Costs," there is the statement that "It is not correct to include such taxes in an economic study, because they are dependent on output or profit and bear no relation to investment."

The writer does not believe that these taxes should be thus disregarded. If these taxes are not correctly included in an economic study, where should they be included? Someone must pay them. It would seem that neglect of them is justifiable only on the assumption that they must be paid out of the allowed return, or in effect by the stockholders, and it is not supposed that the authors would agree to this.

Confining the discussion for the time being to income tax alone, the authors' development of their subject does not seem to bear out the statement that this tax "bears no relation to investment." The authors have quite properly included as the first component of the fixed charges return on the investment rather than bare cost of money. This return is or at least includes the "profit." The income tax depends on this return minus bond interest. The larger the investment, the larger the return; the larger the return, the larger the income tax. Therefore under the authors' method of varying the return (i.e., in dollars) with the investment the income tax does seem to bear a relation to the investment.

The question can best be illustrated by means of the authors' numerical example under the heading, "Set-Up for a Typical Hydro Project." (The writer assumes that "fixed charges" throughout the paper includes return, in spite of the use of the terms "Money, 7 per cent" and "Interest charges, 7 per cent.")

There are two ways of looking at the problem. One is that the company's rates and gross revenue are varied just the proper theoretical amount to yield the specified rate of return, whether the hydro or the steam plant is built. The other is that the rates and gross revenue are the same in both cases (hydro and steam). The inclusion of "return" in fixed charges seems to commit us to the first set-up. That is, the "annual advantage" of $144,800 really means that in order to yield the return which is included in the figures the rate payers would have to pay $144,800 more with the steam plant than with the hydro plant. However, the writer does not believe the answer is correct because the income tax has been omitted. If the financing (i.e., ratio of bonds to stock, net price of bonds, etc.) is the same in the two cases, the income tax in the hydro case will be greater than in the steam case in the ratio of $10,300,000 to $4,700,000 and the advantage of the hydro plant will be correspondingly less than $144,800.

If we change to the assumption that the rates and gross revenue are the same in both cases (hydro and steam), then to compute correctly the relative advantage the writer believes that we must use actual interest instead of nominal return, compute the income tax in each case, and express the final difference in terms of dollars available for dividends per share.

As to gross receipts tax, it seems obvious that if a nominal return is assumed, the revenue and the tax thereon will vary with investment. If the rates and revenue are assumed the same in both cases, the gross receipts tax will also be the same.

The writer's conclusion is that the nominal-fixed-charge method is useful for approximations, but that the rate of fixed charges should include all taxes. Any final decision, however, must be based on a detailed estimate of every individual cost, such as interest and the several taxes.

The authors are to be congratulated and thanked for their clear and complete analysis of the economic balance between hydro and steam.

CARROLL F. MERRIAM.[11] This paper is particularly apropos, because it is too little appreciated that when hydro is properly coordinated with steam, it will generally lead to a total cost of power that is less than that for either source alone. It is frequently assumed that steam and hydro are in direct competition, and consequently the more favorable of the two can be determined by comparison of set-ups made on the assumption that either will be the sole source of power. This paper gives consideration to the mutual advantages, which interlock so closely that steam and hydro are supplementary rather than competitive.

From the standpoint of an operating company it is appreciated that advantages of more or less intangible nature have not been attempted to be evaluated by the authors. The consideration of these is largely a matter of engineering judgment rather than of formal analysis. Those that have had experience in operating a steam-hydro system for maximum over-all economy realize that the two become so intimately allied that practically all problems involve a careful balancing of manifold elements before a true solution can be found. Furthermore, it is impossible to secure the highest degree of economy if contractual restrictions prevent the system from being planned and operated as a unit.

When water power is to be developed, an all-important element in the success or failure of the enterprise is not only the market for energy, but the relation between hydro and steam capacity, as well as the service that hydro can render, not only in kilowatt-hours, but in firm power. Neglect of these facts may lead to failure of a project that otherwise might be a financial success.

Stresses in Boiler Tubes Subjected to High Rates of Heat Absorption

By Wm. L. De Baufre,[1] Lincoln, Neb.

In order to get a more nearly accurate picture of the stresses in thick boiler tubes subjected to high rates of heat absorption, an investigation of the subject, under the supervision of the author, was made using as nearly accurate experimental data as could be found for mild steel and employing theoretically correct relations for the stresses in thick tubes. After calculating the stresses by relations derived for a constant ratio of stress to strain, the results were corrected for plastic flow in the tube wall where the stresses exceeded the elastic limit of mild steel, and also for creep which occurs when mild steel is stressed for long times at elevated temperatures. The stresses were investigated for non-uniform heat absorption around the tube circumference as well as for a uniform rate of heat absorption. Details of the investigation and the results obtained are set forth at length in the paper.

ATTENTION has been called in recent years to the high stresses set up in the tubes of steam boilers due to high rates of heat transfer from burning fuel and products of combustion to water boiling within the tubes. It has been suggested that it would be desirable to use thinner tubes than called for in the A.S.M.E. Boiler Code in order to reduce the total stresses due to heat transfer and internal fluid pressure.

Previous investigations of these stresses have in general been based on approximate data and relations and on a constant ratio of stress to strain, although the calculated stresses have exceeded the elastic limit of the mild steel usually used in such tubes. In order to get a more nearly accurate picture of the stresses in thick boiler tubes subjected to high rates of heat absorption, an investigation was made in the Technical Research Department of International Combustion Engineering Corporation, using as nearly accurate experimental data as could be found for mild steel and employing theoretically correct relations for the stresses in thick tubes. After calculating the stresses by relations derived for a constant ratio of stress to strain, the results were corrected for plastic flow in the tube wall where the stresses exceeded the elastic limit of mild steel, and also for creep which occurs when mild steel is stressed for long times at elevated temperatures. The stresses were investigated for non-uniform heat absorption around the tube circumference as well as for a uniform rate of heat absorption.

The investigation has shown that where the stresses produced by heat transfer and internal fluid pressure exceed the elastic limit of the material near the inner and outer surfaces of the tube wall, the calculated stresses based on perfect elasticity are greatly reduced by plastic flow, but residual stresses are thereby set up when heat transfer ceases and the internal fluid pressure is reduced to zero. Every time a boiler goes into and out of operation, a stress cycle from tension to compression occurs of considerable stress range. This stress range is greatest for the circumferential stress at the inner surface of the tube wall when the tube is heated uniformly. When heated non-uniformly, the axial-stress range may exceed the circumferential-stress range under certain abnormal conditions. It is shown by comparison with experimental data, however, that a boiler tube will not fail within any reasonable period of time by fatigue from these repeated stress reversals.

Before a boiler tube can fail by bursting, all portions of the tube wall must be stressed to a point where more or less rapid creep will occur to rupture. The investigation shows that before this can take place, all heat-transfer stresses will be entirely neutralized by creep. Failure of the tube then occurs by the stresses due to internal pressure only. A measure of the safety of the tube is the ratio of the stress which will cause creep under the mean operating temperature of the tube wall to the mean stress caused by internal fluid pressure. The investigation shows that an increase in tube safety is secured by using thicker rather than thinner tubes than called for by the A.S.M.E. Boiler Code.

An increase in safety may also be obtained by using a material which will not creep until a higher stress is reached, such as a medium-carbon steel in place of a mild carbon steel. Even with mild carbon steel subjected to a very high rate of heat absorption, however, the investigation shows that failure can occur only when the coefficient of heat transfer from the inner surface of the tube wall to the water-steam mixture within the tube is reduced to an abnormally low value. Boiler-tube failures therefore occur by reason of poor circulation of the water-steam mixture within the tubes, by accumulation of scale on the inner surface of the tube wall, by corrosion, or by defective material, rather than by any stresses due to unequal expansion within the tube wall caused by a high rate of heat absorption.

Boiler-Tube Temperatures for Various Rates of Heat Absorption

When heat is transferred through a boiler tube from burning fuel and products of combustion to water boiling within the tube, the tube wall becomes hotter than the inclosed water-steam mixture. The temperature of the tube wall depends upon the rate of heat absorption, the dimensions of the tube, the thermal conductivity of the material, the temperature drop from the

[1] Chairman, Department of Applied Mechanics, University of Nebraska. Mem. A.S.M.E. Mr. De Baufre was graduated from the Baltimore Polytechnic Institute in 1903, and acquired the degrees of E.E., M.E., and M.S. from Lehigh University. He taught at Baltimore Polytechnic for several years, and during the latter part of this period was head of the Department of Engineering there. For a number of years thereafter he was mechanical engineer with the U. S. Naval Engineering Experiment Station, leaving this work to become professor of mechanical engineering and later chairman of the Mechanical Engineering Department at the University of Nebraska. In 1926 he became head of the Technical Research Department, International Combustion Engineering Corporation, in which capacity, among other activities, he supervised the investigation described in the present paper.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

inner surface to the water boiling within the tube, and the pressure under which steam is being generated. The temperatures of the outside and inside surfaces of mild-steel boiler tubes are given in Tables 1, 2, and 3 for several rates of heat transfer with 3-, 3.5-, and 4-in. tubes such as might be used for the steam pressures tabulated, the thinnest tube wall corresponding to that specified by the A.S.M.E. Boiler Code.

In calculating the data for the above-mentioned tables, the temperature of saturated steam was taken from Keenan's "Steam Tables" published by the A.S.M.E. The temperature drop from the inner surface of the tube wall through the water film to the water boiling within the tube was calculated by the formula

$$\Delta T = \frac{Q}{U}\frac{r_2}{r_1}$$

where Q = heat-absorption rate to outside of tube, Btu per hr per sq ft
r_1 = inside radius of tube, inches
r_2 = outside radius of tube, inches
U = heat-transfer factor through water film, Btu per hr per sq ft per deg F, and
ΔT = temperature drop through water film, deg F.

The heat-transfer factor U was taken equal to 3000 Btu per hr per sq ft per deg F, a value which has been found to exist under favorable circumstances between condensing steam and evaporating water. Measurements by Kreisinger and Barkley upon a Heine boiler, as described in U. S. Bureau of Mines Technical Paper 114, indicate a higher heat-transfer factor, so that the value selected is considered conservative for good operating conditions.

The temperature of the inside surface of the tube wall is equal to the saturated-steam temperature plus the temperature drop through the water film. The temperature of the outside surface of the tube wall is equal to the temperature of the inside surface plus the temperature drop through the tube wall as calculated by the formula derived in Appendix No. 1, namely:

$$T_2 - T_1 = \frac{Qr_2}{12\lambda}\log_e\frac{r_2}{r_1}$$

where Q = rate of heat absorption to outside surface of tube, Btu per hr per sq ft
λ = thermal conductivity of metal in tube wall, Btu per hr per sq ft per deg F for 1 ft thickness
T_1 = temperature of inside surface, deg F
T_2 = temperature of outside surface, deg F.

The thermal conductivity λ was selected in accordance with the data in Appendix No. 2 for the average temperature in the tube wall. This necessitated a trial-and-error method of computation. The outside-surface temperature was first assumed and the correctness of the assumption then determined by substituting the corresponding value of the thermal conductivity in the above formula.

The data in Tables 1, 2, and 3 are of interest in showing the rise of the tube-wall temperature with higher steam pressures and with increased rates of heat absorption. In water-cooled furnaces, the rate of heat absorption in the first rows of the boiler tubes varies from 30,000 to 60,000 Btu per hr per sq ft. In furnaces without water cooling, the rate of heat absorption in the first rows of boiler tubes may be higher and may reach 90,000 Btu per hr per sq ft due to the higher temperatures in refractory-lined furnaces. For a discussion of heat absorption by water-cooled surfaces exposed to radiation in a furnace, see "Heat Absorption in Water-Cooled Furnaces," by the present author, in Trans. A.S.M.E., Vol. 53 (1931), pp. 253–264.

Calculated Stresses in a Thick Boiler Tube

As shown in Appendix No. 1, the total radial, circumferential, and axial stresses at any point in a tube wall may be obtained by adding the stresses calculated separately for fluid pressure and for heat transfer. The formulas as derived in Appendix No. 1 are:

For fluid pressure:

$$p_p = \frac{r_2^2 - r^2}{r_2^2 - r_1^2}\frac{r_1^2 p_1}{r^2}$$

$$t_p = \frac{r_2^2 + r^2}{r_2^2 - r_1^2}\frac{r_1^2 p_1}{r^2}$$

$$s_p = \frac{r_1^2 p_1}{r_2^2 - r_1^2}$$

For heat transfer:

$$p_t = \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e\frac{r_2}{r_1}}\left[-(r_2^2\log_e r_2 - r_1^2\log_e r_1) + \frac{r_1^2 r_2^2}{r^2}\log_e\frac{r_2}{r_1} + (r_2^2 - r_1^2)\log_e r\right]$$

$$t_t = \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e\frac{r_2}{r_1}}\left[(r_2^2\log_e r_2 - r_1^2\log_e r_1) - (r_2^2 - r_1^2) + \frac{r_1^2 r_2^2}{r^2}\log_e\frac{r_2}{r_1} - (r_2^2 - r_1^2)\log_e r\right]$$

$$s_t = \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e\frac{r_2}{r_1}}\left[2(r_2^2\log_e r_2 - r_1^2\log_e r_1) - (r_2^2 - r_1^2) - 2(r_2^2 - r_1^2)\log_e r\right]$$

For fluid pressure and heat transfer:

$$p = p_p + p_t$$
$$t = t_p + t_t$$
$$s = s_p + s_t$$

where r_1 = inside radius of tube, inches
r_2 = outside radius of tube, inches
p_1 = inside fluid pressure, lb per sq in. (outside fluid pressure being zero)
T_1 = temperature of inside surface, deg F
T_2 = temperature of outside surface, deg F
$1/m$ = Poisson's ratio
E = coefficient of elasticity at mean tube-wall temperature, lb per sq in.
α = coefficient of thermal expansion at mean tube-wall temperature, inch per inch per deg F
p_p = radial compressive stress at radius r due to fluid pressure, lb per sq in.
t_p = circumferential tensile stress at radius r due to fluid pressure, lb per sq in.
s_p = axial tensile stress at radius r due to fluid pressure, lb per sq in.
p_t = radial compressive stress at radius r due to heat transfer, lb per sq in.
t_t = circumferential tensile stress at radius r due to heat transfer, lb per sq in.
s_t = axial tensile stress at radius r due to heat transfer, lb per sq in.

p = total radial compressive stress at radius r, lb per sq in.

t = total circumferential tensile stress at radius r, lb per sq in.

s = total axial tensile stress at radius r, lb per sq in.

By means of the foregoing formulas, the stresses were calculated in an exceptionally thick boiler tube required for a very high steam pressure, 1840 lb gage. The diameter of this tube is

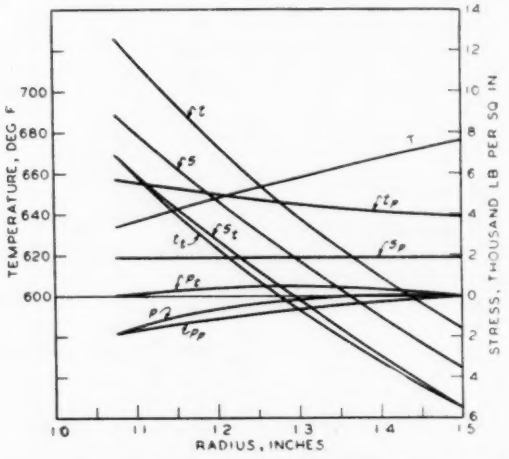

FIG. 1 CALCULATED STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 30,000 BTU PER HR PER SQ FT

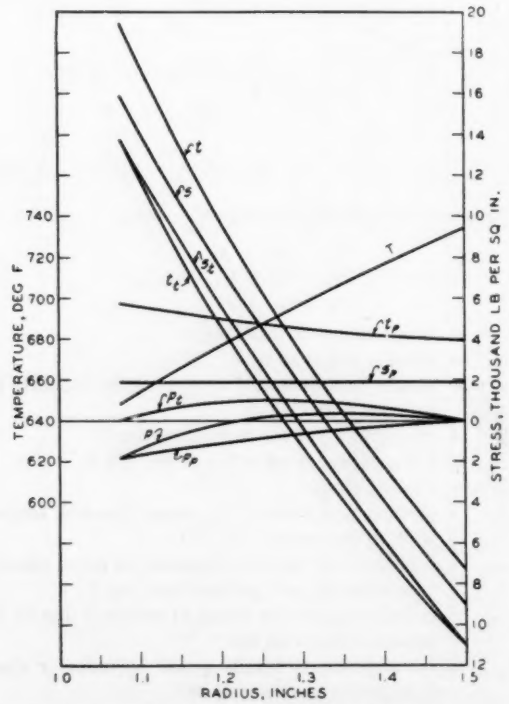

FIG. 2 CALCULATED STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 60,000 BTU PER HR PER SQ FT

3 in. and its thickness is 0.425 in., so that $r_2 = 1.5$ in. and $r_1 = 1.075$ in. The resulting stresses are shown in Figs. 1, 2, and 3 for rates of heat absorption of 30,000, 60,000, and 90,000 Btu per hr per sq ft of outside surface. The temperatures in the tube wall are also shown in Figs. 1, 2, and 3 for the several rates

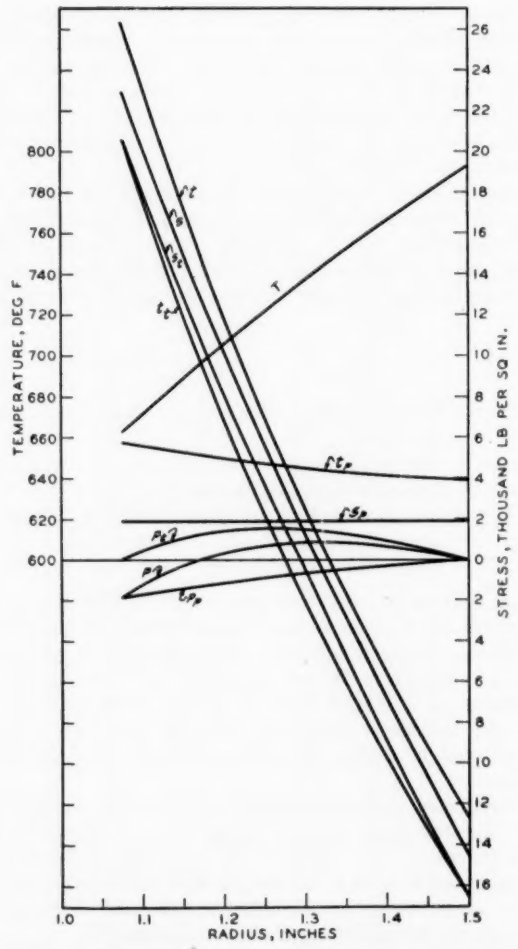

FIG. 3 CALCULATED STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

of heat absorption. The maximum and minimum temperatures are as follows:

Rate of heat absorption, Btu per hr per sq ft	Saturated-steam temp., deg F	Temperature of inside surface, deg F	Temperature of outside surface, deg F
30,000	620	634.0	676.5
60,000	620	647.9	734.1
90,000	620	661.9	792.5

In calculating the stresses due to heat transfer, it was necessary to select proper values of the modulus of elasticity E, the coefficient of thermal expansion α, the coefficient of thermal conductivity λ, and Poisson's ratio $1/m$. As explained in Appendix No. 2, the last-mentioned quantity was taken as 0.30, while the values of the other three quantities were taken to correspond to the mean temperature in the tube wall.

In Figs. 1, 2, and 3 the stresses due to fluid pressure are the same for all three rates of heat absorption. The radial compressive stress p_p varies from the internal fluid pressure of 1840 lb per sq in. at the inside surface of the tube wall to zero at the outside surface. The circumferential tensile stress t_p varies from a maximum of 5726 lb per sq in. at the inside surface to a minimum of 3886 lb per sq in. at the outside surface. The summation of the circumferential tensile stress over the tube wall is equal to the total internal fluid pressure along a radius, that is,

$$\int_{r_1}^{r_2} t_p dr = p_1 r_1$$

The axial tensile stress is constant over the tube-wall cross-section and is equal to 1943 lb per sq in. The product of this axial stress and the cross-sectional area of the tube wall is equal to the total axial internal fluid pressure.

In Figs. 1, 2, and 3 the stresses due to heat transfer differ greatly for the three rates of heat absorption selected. In general, the circumferential and axial stresses t_t and s_t vary from the same maximum tensile stress at the inside surface to the same maximum compressive stress at the outside surface, but do not coincide at points within the tube wall. The maximum tensile stress at the inside surface is greater than the maximum compressive stress at the outside surface as shown in the following table:

Rate of heat absorption, Btu per hr per sq ft	Maximum circumferential and axial tensile stress at inside surface, lb per sq in.	Maximum circumferential and axial compressive stress at outside surface, lb per sq in.
30,000	6,841	5,486
60,000	13,721	11,004
90,000	20,618	16,536

The summations of the circumferential and axial stresses over the tube wall are each equal to zero. The radial stress p_t due to heat transfer only is zero at both the inside and outside surfaces; within the tube wall, the metal is in tension radially, but the maximum tension is small.

Adding the stresses due to fluid pressure and to heat transfer for the several rates of heat absorption, we find the total circumferential tensile stress at the inside surface of the tube wall to be the greatest stress in the material. The total circumferential stress varies from this maximum value in tension at the inside surface through zero at a point within the wall to a much lower maximum compressive stress at the outside surface. Its summation over the tube wall is equal to the total internal fluid pressure along a radius, that is,

$$\int_{r_1}^{r_2} t dr = p_1 r_1$$

The maximum total axial stress also occurs at the inside surface of the tube wall and varies from this maximum value in tension at the inside surface to a maximum value in compression at the outside surface, its summation over the cross-section of the tube wall being equal to the axial internal fluid pressure, that is,

$$\int_{r_1}^{r_2} s r dr = \frac{p_1 r_1^2}{2}$$

The total radial stress is low and will not receive further consideration.

The summation over the tube wall of the total stress due to both heat transfer and internal fluid pressure is evidently equal to the summation of the stress due to internal fluid pressure only.

The maximum values calculated for the total circumferential and axial tensile stresses at the inside surface of the tube wall are as follows:

Rate of heat absorption, Btu per hr per sq ft	Maximum circumferential tensile stress, lb per sq in.	Maximum axial tensile stress, lb per sq in.
30,000	12,567	8,784
60,000	19,447	15,664
90,000	26,344	22,561

These stresses were calculated on the assumption of perfect elasticity. By reference to Fig. 37 in Appendix No. 2 in which stress-strain diagrams are given for the mean tube wall temperatures at the several rates of heat transfer, it will be seen that the above stresses extend into regions of plastic flow beyond the elastic limits of mild steel at these temperatures. This fact is also shown by Fig. 36 in Appendix No. 2 giving the proportional limit stress of mild steel at elevated temperatures. Hence these calculated stresses will not be reached by reason of plastic flow in the tube wall adjacent to the inner surface.

Probable Circumferential Stresses in a Thick Boiler Tube

The variation of the circumferential stress in a thick boiler tube is due to relative strains in the tube wall. Thus, the heat-transfer stress is due entirely to relative expansion of the inner and outer portions of the tube wall. The variation in the fluid pressure stress is due to the inner portions of the tube wall first slightly elongating before the outer portions can offer any resistance to the internal pressure. Hence if we divide the stresses in Figs. 1, 2, and 3 by the modulus of elasticity of mild steel, we may consider the results as representing the deformations in the several directions, although the maximum stresses indicated in these figures are not reached owing to plastic flow.

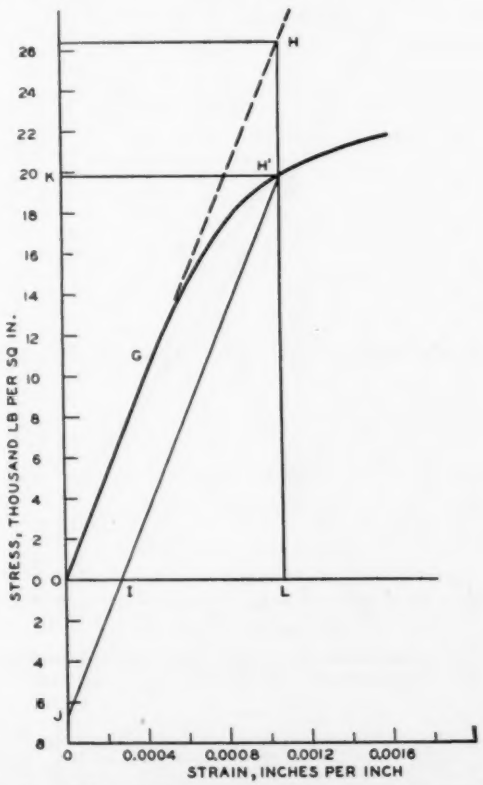

Fig. 4 Stress-Strain Diagram for Mild Steel at 717 F Mean Temperature of Tube Wall for Heat Absorption of 90,000 Btu per Hr per Sq Ft

Now refer to Fig. 4 where the point H represents the circumferential tensile stress of 26,300 lb per sq in. calculated for the constant stress-strain ratio represented by the straight line OH having a slope equal to the modulus of elasticity E. The actual stress-strain curve deviates from the straight line OH; so that for the same strain, the actual stress is 19,800 lb per sq in. as represented by the point H'. In this way, the calculated stresses in Figs. 1, 2, and 3 were reduced to more probable values whenever they fell on the straight line OH above the actual stress-strain diagram OH'.

It may be questioned whether this construction is entirely correct due to the fact that the actual stress-strain diagram was determined from experimental data obtained by loading a test specimen in one direction only, while in the boiler tube under discussion stresses exist in three directions at right angles. One of the three stresses, however, is very small, namely, the radial stress. Under this condition it is probable that the proportional limit for the circumferential tensile stress is but little affected by the axial tensile stress, although the strains are all reduced in a nearly constant ratio as determined by Poisson's ratio and a nearly proportionate relation between the circumferential and axial stresses. Such a distortion of the stress-strain diagram does not affect the accuracy of the construction.

The upper curve of Fig. 7 has been reproduced from the calculated circumferential-stress curve of Fig. 3 for a heat-absorption rate of 90,000 Btu per hr per sq ft. The point A' was plotted at 19,800 lb per sq in. vertically below the point A representing the calculated stress of 26,300 lb per sq in. By a similar procedure to that explained above for determining the point A' corresponding to the point A, other points on the curve $A'B$ were obtained. Below the point B there is no appreciable plastic flow of the material. The new curve $A'BC$, however, does not fulfil the condition

$$\int_{r_i}^{r_2} t dr = p_i r_i$$

But by moving the zero line down in order to increase the positive tensile stresses and decrease the negative compressive stresses, a new position is found where this condition is again fulfilled 689 lb per sq in. below the old position.

Replotting the circumferential-stress curve to the new zero line in Fig. 8 raises the maximum stress from 19,800 lb per sq in. to 20,489 lb per sq in. as represented by the point A'. Referring to the stress-strain diagram of Fig. 4, it is seen that plastic flow will lower this stress to 19,900 lb per sq in. Similarly, the other stresses along the line $A'B$ will be reduced to those represented by $A''B$. This necessitates a further lowering of the zero line in order to meet the condition

$$\int_{r_i}^{r_2} t dr = p_i r_i$$

But as this lowering is only 82 lb per sq in., no further corrections are considered necessary for plastic flow.

The final circumferential-stress curve is plotted in Fig. 9 as $A''BC'$ in comparison with the original calculated curve AC. A

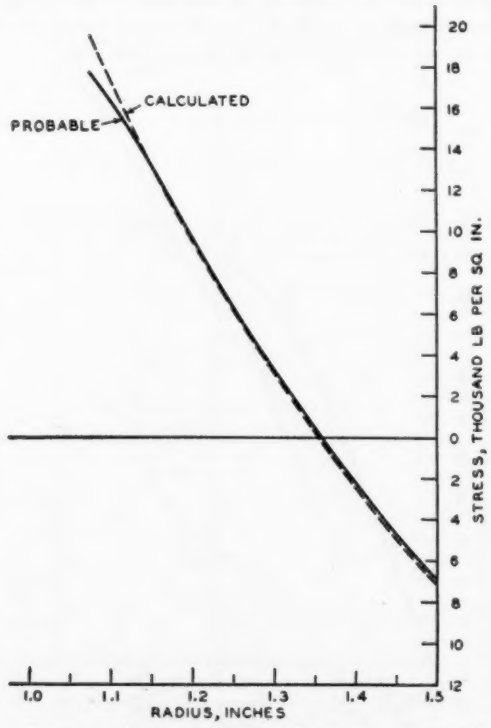

FIG. 5 PROBABLE CIRCUMFERENTIAL STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 60,000 BTU PER HR PER SQ FT

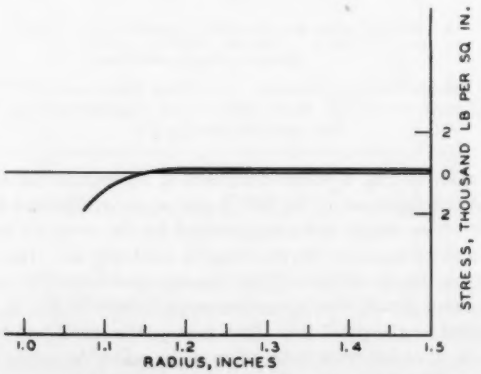

FIG. 6 RESIDUAL CIRCUMFERENTIAL STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 60,000 BTU PER HR PER SQ FT

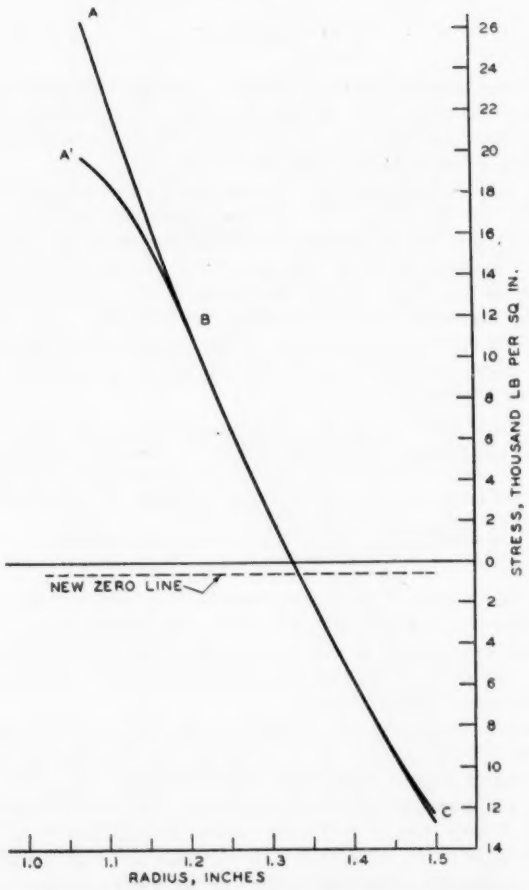

FIG. 7 FIRST CORRECTION OF CIRCUMFERENTIAL STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

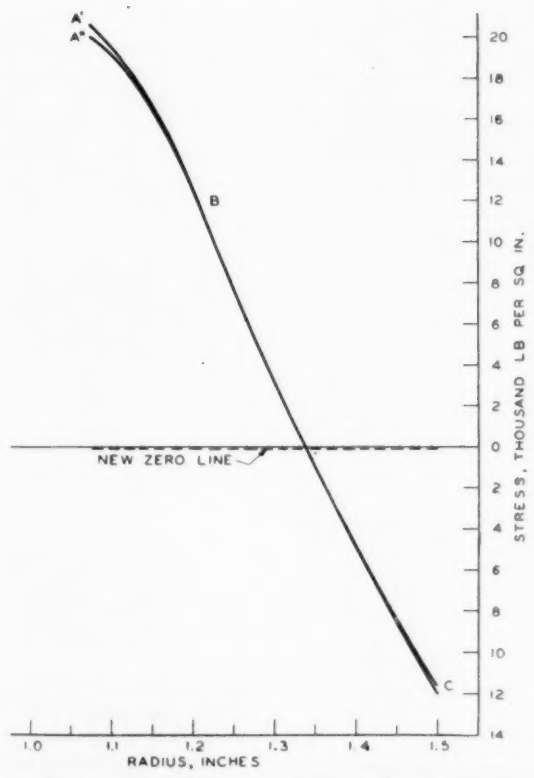

FIG. 8 SECOND CORRECTION OF CIRCUMFERENTIAL STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

comparison of these two curves shows that the probable maximum circumferential tensile stress at the inside surface of the tube wall is about 6300 lb per sq in. less than the calculated stress for perfect elasticity, while farther within the tube wall the probable stresses are about 800 lb per sq in. higher than calculated. In other words, when portions of the tube wall tend to be stressed above the proportional limit of the material, the stresses in these portions are reduced by plastic flow below the values calculated on the assumption of perfect elasticity. A considerable reduction in tensile stress adjacent to the inside surface of the tube wall is balanced by a small additional tensile stress distributed over the remaining portion of the tube wall where the proportional limit of the material is not exceeded.

In a similar way the modifications in the circumferential stresses due to plastic flow adjacent to the inside surface of the tube wall were obtained for the heat-absorption rate of 60,000 Btu per hr per sq ft. The results are shown in Fig. 5. No modifications were made in the stresses for the heat-absorption rate of 30,000 Btu per hr per sq ft because the maximum stresses exceeded but slightly the proportional limit of the material at the operating temperatures.

RESIDUAL CIRCUMFERENTIAL STRESSES DUE TO PLASTIC FLOW

If a material is subjected to plastic flow by being stressed above the elastic limit, it takes a permanent set; that is, the material will not come back to its original length when the forces producing the stress are removed. In a tube wall subjected to high rates of heat absorption, plastic flow and consequently a permanent set occur only in portions of the material near the inner and outer surfaces. Therefore residual stresses will be produced in the material when heat transfer ceases and the internal fluid pressure is reduced to zero.

This may be seen by referring to Fig. 4. When a tensile stress corresponding to the point H' above the elastic limit of the material is removed, the strain will not retrace the line $H'GO$ but will trace the line $H'I$ parallel to GO. The strain OI is the permanent set remaining in the material when the stress is reduced to zero. In order to return the material to its original length, a compressive stress equal to OJ must be applied. The deformation OL was originally produced by the stress OK; but to return the material to its original length requires a change in stress equal to KJ.

In a tube wall the tensile stress at the inside surface follows the line $H'IJ$ when heat transfer ceases and the internal fluid pressure is reduced to zero. Farther within the tube wall, however, where the material was not strained beyond the elastic limit, the stress returns along the line GO. When the stress at the inside surface has reached zero at the point I, other portions of the tube wall are still in tension. Consequently the portion of the tube wall adjacent to the inside surface will be subjected to a compressive stress by other portions of the tube wall approaching zero stress. Equilibrium will occur when the summation of the compressive stresses set up adjacent to the inside surface just balances the summation of the tensile stresses remaining in other portions of the tube wall.

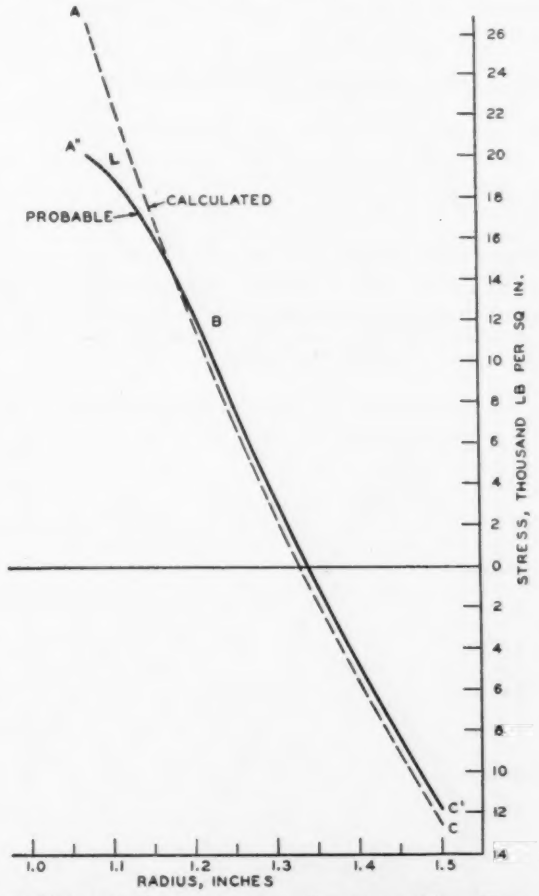

FIG. 9 PROBABLE CIRCUMFERENTIAL STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

The residual stresses in the boiler tube under discussion for the heat-absorption rate of 90,000 Btu per hr per sq ft were calculated from the curves in Fig. 9 by first assuming all portions of the tube wall to return to their original lengths and then adjusting the zero line to balance the compressive and tensile stresses. For illustration, consider point L in Fig. 9 at a stress

of 19,800 lb per sq in. which is represented by point H' on the stress-strain diagram of Fig. 4. When the material at this point in the tube wall is returned to its original length, the stress is represented by OJ, or 6600 lb per sq in. in compression. This stress was plotted at point M in Fig. 10. Several additional points obtained in the same manner gave the broken-line curve. In order to make the summation of the residual stresses equal to zero, this curve was moved up 800 lb per sq in. to the position shown by the solid line. The solid line indicates a residual compressive stress of 6300 lb per sq in. at the inside surface of the tube wall. At a distance of 0.09 in. from the inside surface, the residual stress is zero. Over a large portion of the tube wall there is a residual tensile stress of 800 lb per sq in.

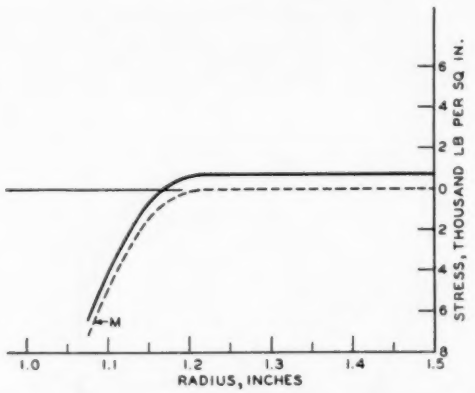

FIG. 10 RESIDUAL CIRCUMFERENTIAL STRESSES IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

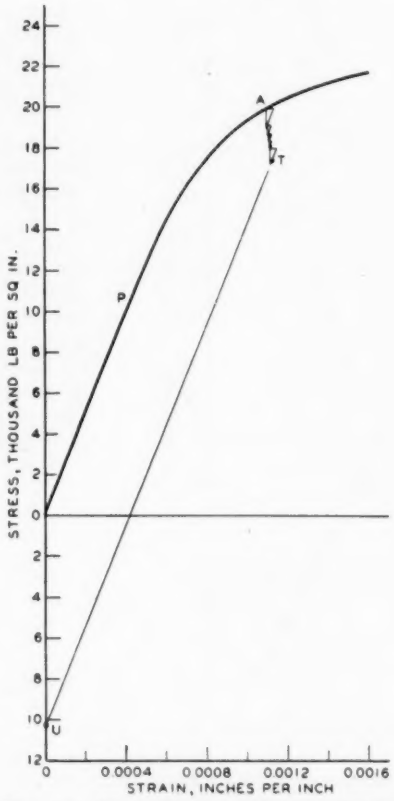

FIG. 12 STRESS-STRAIN DIAGRAM ILLUSTRATING CREEP

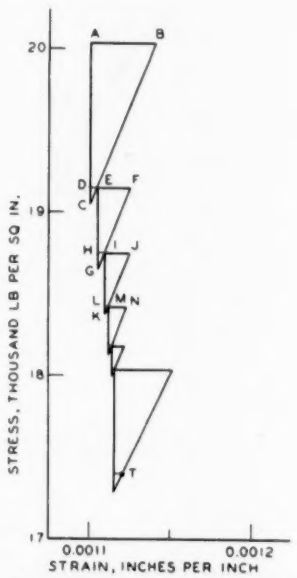

FIG. 13 ENLARGEMENT OF PORTION OF STRESS-STRAIN DIAGRAM SHOWN IN FIG. 12

Dividing 800 lb per sq in. by the modulus of elasticity of the material, 24.7×10^6 lb per sq in., gives 32.4×10^{-6} in. per inch as the permanent deformation of the tube as a whole. The outside diameter of the tube will therefore be increased from 3 in. to $3 + (3 \times 32.4 \times 10^{-6}) = 3.000097$ in. This increase in diameter will increase the stress due to internal fluid pressure, but the change is so small as to be negligible.

In Fig. 6 are shown the residual stresses for a heat-absorption rate of 60,000 Btu per hr per sq ft obtained in a manner similar to that explained for the higher heat-absorption rate. For a heat-absorption rate of 30,000 Btu per hr per sq ft, the residual stresses are negligible.

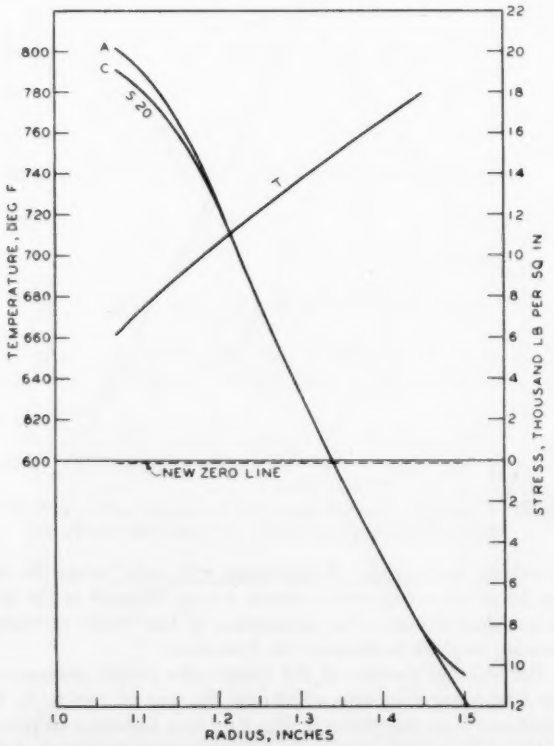

FIG. 11 REDISTRIBUTION OF CIRCUMFERENTIAL STRESSES IN TUBE WALL AFTER 20 HOURS' OPERATION AT HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

EFFECT OF CREEP UPON CIRCUMFERENTIAL STRESSES

The plastic flow above the elastic limit represented by the upper part of the stress-strain diagram of Fig. 4 corresponds to the comparatively rapid rate of loading used in an ordinary tension test of material. When the load on a test specimen is maintained for a long period, additional plastic flow will occur if the stress is above the creep-limit stress corresponding to the temperature of the material. The rate of creep in inches per inch per hour will vary for mild steel with the stress and the temperature somewhat as shown in Fig. 39 of Appendix No. 2. Sometimes this secondary plastic flow is called secondary creep and the first plastic flow is called primary creep. In speaking of creep in this paper, secondary plastic flow will be meant.

By reference to Fig. 39 in Appendix No. 2, it will be seen that the circumferential tensile stress near the inside surface of the tube wall is above the creep limit of the material for the heat-absorption rate of 90,000 Btu per hr per sq ft. Actual flow of the material is prevented, however, by adjacent portions of the tube wall which are not stressed beyond the creep limit. What happens to the stress under these conditions? Creep tests are conducted by subjecting a test specimen to a constant stress

and measuring the elongation at intervals of time. No tests have apparently been made in which the elongation was maintained constant and the variable stress measured. The stress, however, would undoubtedly decrease with time.

The following method was employed to calculate the reduction in stress with time in those portions of the tube wall where the stress exceeded the creep limit stress. The redistribution of

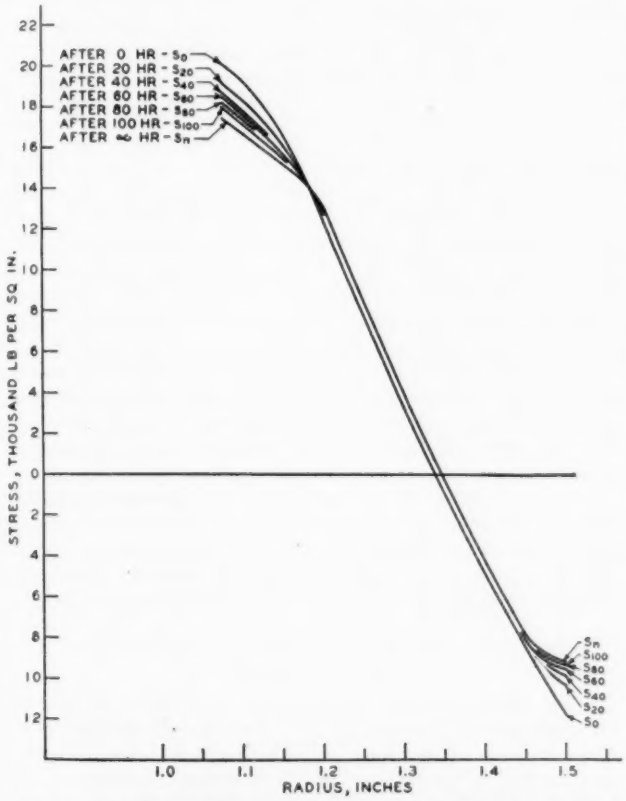

FIG. 14 REDISTRIBUTION OF CIRCUMFERENTIAL STRESSES IN TUBE WALL AFTER VARIOUS PERIODS OF OPERATION AT HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

stress after 20 hr of operation was first calculated. Referring to Fig. 11, the upper curve for zero hours of operation was reproduced from Fig. 9. At point *A*, the stress is 20,031 lb per sq in. after the initial plastic flow has occurred, but before creep has taken place. The temperature at this point in the tube wall is 662 F as shown by the temperature curve. Referring to Fig. 39 in Appendix No. 2, it will be seen that if the stress were kept at 20,031 lb per sq in., creep would occur at the rate of 0.000002 in. per inch per hr. For 20 hr the total creep would be 0.000040 in. per inch as represented by the line *AB* in Fig. 13. If this creep actually occurred under constant stress and the stress were then reduced until the material reached its original length, the reduction in stress would follow the line *BC* parallel to the portion *PO* of the stress-strain diagram below the proportional limit of the material. The point *C* directly under the original point *A* would represent the stress when the material reached its original length. This point was taken to represent the stress which would be reached after 20 hr if the elongation were kept constant. The reduction in stress represented by *AC* may be calculated from the deformation *AB* and the modulus of elasticity of the material; thus, $AC = 0.000040 \times 24.7 \times 10^6 = 988$ lb per sq in. Hence point *C* in Fig. 11 is 20,031 — 988 = 19,043 lb per sq in.

The stresses after 20 hr at several other points in the tube wall where the original stresses exceeded the creep limit stresses, were calculated in a similar manner and plotted on Fig. 11. For the curve so obtained, however, the summation of the stresses across the tube wall do not balance the internal fluid pressure along a radius. To obtain this balance, the zero line was moved down 97 lb per sq in.

This depression of the zero line is represented by the distance *CD* in Fig. 13. The tube as a whole expands an amount *DE* inch per inch due to reduction in stress near the inside surface by creep and consequent increase of stress over the remaining portions of the tube wall. This expansion may be calculated from the stress increase of 97 lb per sq in. and the modulus of elasticity of the material, thus, $97/(24.7 \times 10^6) = 0.0000039$ in. per inch. The increase in outside diameter during 20 hr would be $3 \times 0.0000039 = 0.0000117$ in.

During the second 20 hr, creep will take place in a similar manner to that explained for the first 20 hr, but at a slower rate, due to the reduction in stress which has occurred during the first 20 hr. The calculations for the second 20 hr are represented by the stress-strain diagram *EFGHI* in Fig. 13. Calculations for additional intervals of 20 hr were made until a total interval of 100 hr was reached. The resulting stress-distribution curves are shown in Fig. 14, the various time intervals being denoted by s_0, s_{20}, etc. The change in stress from 80 to 100 hr is very small, indicating that the creep-limit stress has nearly been reached in the portions of the tube wall where the stresses exceed this limit. The next step taken was to determine the stress-distribution curve s_n at the creep limit, which would be reached only after an infinite interval of time. This was done by reducing all stresses for the s_{100} curve where they were above

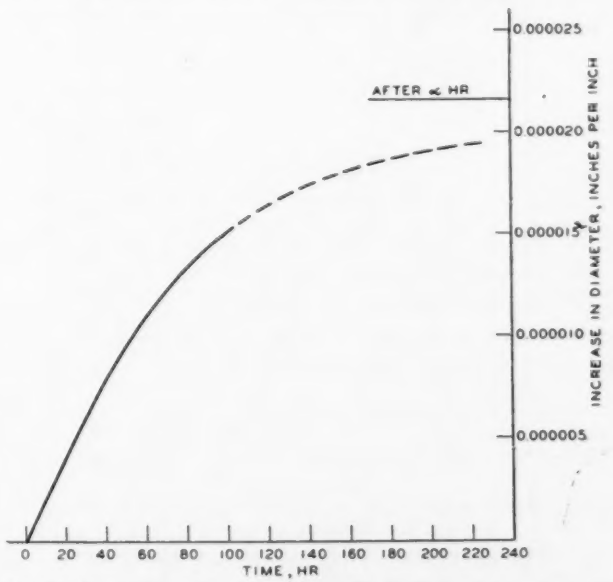

FIG. 15 INCREASE IN TUBE DIAMETER WITH TIME OF OPERATION AT HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

the creep limit to the creep limit, and then adjusting the zero line. The increase in outside diameter of the tube as the higher stresses are reduced by creep is shown in Fig. 15.

RESIDUAL CIRCUMFERENTIAL STRESSES AFTER CREEP

Owing to creep in those portions of the tube wall where the stresses exceeded the creep-limit stress of the material, the residual stresses after heat transfer ceases and the internal fluid pressure is removed will be altered from those shown in Fig. 10

for conditions before creep has taken place. The residual stresses corresponding to the creep-limit curve in Fig. 14 are shown by the solid line in Fig. 16. The broken-line curve is reproduced from Fig. 10 and shows the residual stresses before creep has occurred. The solid-line curve was obtained in a

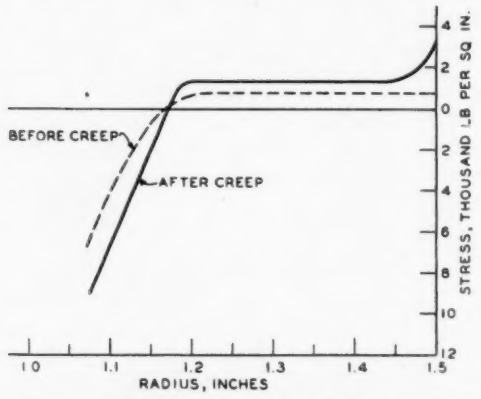

FIG. 16 RESIDUAL CIRCUMFERENTIAL STRESSES IN TUBE WALL AFTER OPERATION FOR INFINITE TIME AT HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

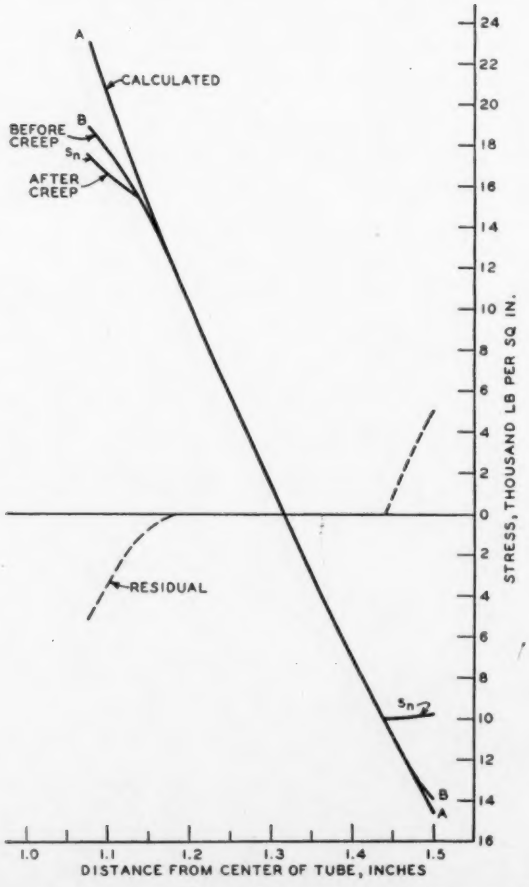

FIG. 17 AXIAL STRESSES IN TUBE WALL FOR UNIFORM HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

manner similar to that explained for the broken-line one. Thus, point *T* in Fig. 12 represents the condition in the material at the inner surface of the tube wall after the creep-limit stress has been reached. As heat transfer ceases and the internal fluid pressure is produced to zero, the stress and strain will follow the line *TU* drawn parallel to *PO*. The point *U* will represent the compressive stress required to return the material to its original length. A curve was first drawn for the residual stresses, assuming all portions of the tube wall to be returned to their original lengths. The zero line was then adjusted to obtain a balance between the tensile and compressive stresses. The final location of the residual-stress curve was thus obtained as shown by the solid line in Fig. 16.

PROBABLE AND RESIDUAL AXIAL STRESSES IN A THICK BOILER TUBE

At the heat-absorption rate of 30,000 Btu per hr per sq ft the calculated axial stresses in Fig. 1 are all within the proportional limit of mild steel. At 60,000 Btu per hr per sq ft the calculated axial stresses in Fig. 2 exceed the proportional limit near the inside surface of the tube wall, but corrections for plastic flow were applied only to the axial stresses calculated for 90,000 Btu per hr per sq ft in Fig. 3. The axial-stress gradients in the tube wall are shown by the curves in Fig. 17. The curve *AA* represents the axial stresses as calculated for perfect elasticity. The curve *BB* represents the axial stresses as modified by the initial plastic flow of the material. The curve $s_n s_n$ represents the axial stresses after a long period of time when secondary plastic flow has occurred to reduce all stresses above the creep limit to the creep-limit stresses. The residual axial stresses after creep has occurred are represented by the broken lines. These modifications in the calculated stresses due to plastic flow were made in the same manner as explained for the circumferential stresses. It happens, however, that no adjustment of the zero line was necessary because the reduction in tensile stresses just balanced the reduction in compressive stresses.

STRESSES IN A BOILER TUBE SUBJECTED TO NON-UNIFORM HEAT ABSORPTION

When the rate of heat absorption is not uniform around the circumference of a boiler tube, as is the case with the first rows of boiler tubes subjected to radiation on one side only from the burning fuel in the furnace, the circumferential stresses at the place of maximum heat absorption will evidently not differ greatly from those determined as if the maximum rate of heat absorption were uniform around the tube. The axial stress, however, will be increased under certain conditions of non-uniform heat absorption and may exceed the circumferential stress under abnormal conditions.

Thus, when heat is absorbed at a high rate on the furnace side of a boiler tube and at a low rate on the opposite side, the average metal temperature on the furnace side will be greater than on the opposite side. This causes a greater expansion on the furnace side of the tube than on the other side, so that the tube will bend into an arc of a circle convex to the furnace. If restrained from bending, axial stresses will be set up due to the differences in expansion on the two sides of the tube caused by the unequal temperature rises. These axial stresses will be in addition to those calculated by assuming a uniform rate of heat absorption around the tube. If the tube is allowed to bend, these additional axial stresses will be more or less relieved.

The following analysis of the axial stresses in a boiler tube subjected to non-uniform heat absorption will be based on assumed absorption rates of 30,000, 60,000, and 90,000 Btu per hr per sq ft around 180 deg of the circumference while the remaining 180 deg receives no heat. The results will then be modified to show the effects of a less abrupt change from the maximum to the minimum rate of heat absorption. Under these assumptions, the temperatures in the tube wall will be as follows:

Rate of heat absorption, Btu per hr per sq ft	Furnace side of tube: Temperature of inside surface, deg F	Furnace side of tube: Temperature of outside surface, deg F	Rear side of tube: Temperature of whole wall, deg F
30,000	634.0	676.5	620
60,000	647.9	734.1	620
90,000	661.9	792.5	620

The axial stresses in the tube wall will first be calculated for the tube before any bending has taken place. These axial stresses will tend to bend the tube, and their bending moment will be determined. It will then be assumed that the tube bends until these bending moments are reduced to zero, and the redistribution of stresses will be found. Corrections will be made for plastic flow of the material in certain portions of the tube wall, and the residual axial stresses will be determined.

Calculated Axial Stresses Before Bending in a Thick Boiler Tube Heated on One Side Only

The larger longitudinal expansion due to the greater temperature rise on the furnace side of a boiler tube is resisted by the smaller expansion on the opposite side. This sets up compressive stresses in the tube wall on the furnace side and tensile stresses in the tube wall on the opposite side. The summation of the tensile stresses will exceed the summation of the compressive stresses by the total axial internal fluid pressure.

The following formulas were derived in Appendix No. 1, for calculating the axial stresses in the tube wall on the furnace side and on the opposite side of a boiler tube absorbing heat through 180 deg only:

$$s_1 = A - s_3$$

$$s_2 = B - s_3$$

$$s_3 = \frac{r_1^2 p_1}{r_2^2 - r_1^2} + \frac{A}{6}\frac{r_2 + 2r_1}{r_2 + r_1} + \frac{B}{6}\frac{2r_2 + r_1}{r_2 + r_1}$$

$$A = (T_1 - T_3)\alpha_1 E_1 - t_1/m$$

$$B = (T_2 - T_3)\alpha_2 E_2 + t_2/m$$

$$t_1 = (T_2 - T_1)\alpha E/2$$

$$t_2 = -(T_2 - T_1)\alpha E/2$$

where r_1 = inside radius of tube wall, inches

r_2 = outside radius of tube wall, inches

p_1 = internal fluid pressure, lb per sq in. (outside fluid pressure being zero)

T_1 = temperature at inside surface of tube wall on furnace side, deg F

T_2 = temperature at outside surface of tube wall on furnace side, deg F

T_3 = temperature of tube wall on opposite to furnace side, deg F

E_1 = modulus of elasticity corresponding to T_1, lb per sq in.

E_2 = modulus of elasticity corresponding to T_2, lb per sq in.

E = modulus of elasticity corresponding to $(T_1 + T_2)/2$, lb per sq in.

α_1 = coefficient of thermal expansion corresponding to T_1, inch per inch per deg F

α_2 = coefficient of thermal expansion corresponding to T_2, inch per inch per deg F

α = coefficient of thermal expansion corresponding to $(T_1 + T_2)/2$, inch per inch per deg F

$1/m$ = Poisson's ratio

s_1 = axial compressive stress at r_1 on furnace side, lb per sq in.

s_2 = axial compressive stress at r_2 on furnace side, lb per sq in.

s_3 = axial tensile stress in tube wall on opposite to furnace side, lb per sq in.

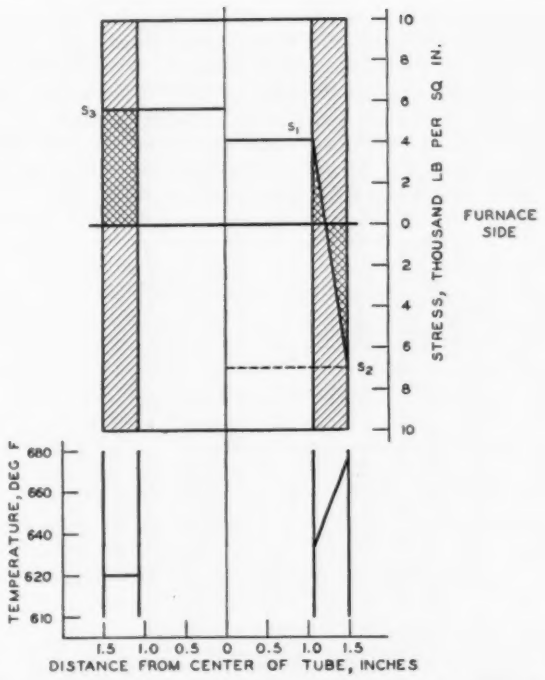

Fig. 18 Axial Stresses in Tube Wall Before Bending for Non-Uniform Heat Absorption of 30,000 Btu per Hr per Sq Ft

To illustrate the use of the above formulas, a numerical example will be worked out for a heat-absorption rate of 30,000 Btu per hr per sq ft. Under these conditions, we have

r_1 = 1.075 in.

r_2 = 1.5 in.

p_1 = 1,840 lb per sq in.

T_1 = 634.0 F

T_2 = 676.5 F

T_3 = 620.0 F

E_1 = 25.8×10^6 lb per sq in. from Fig. 35

E_2 = 25.3×10^6 lb per sq in. from Fig. 35

E = 25.5×10^6 lb per sq in. from Fig. 35

α_1 = 7.86×10^{-6} inch per inch per deg F from Fig. 40

α_2 = 7.97×10^{-6} inch per inch per deg F from Fig. 40

α = 7.92×10^{-6} inch per inch per deg F from Fig. 40

$1/m$ = 0.30

$$t_1 = \frac{676.5 - 634.0}{2} \times 7.92 \times 10^{-6} \times 25.5 \times 10^6 = 4292$$ lb per sq in.

t_2 = —4292 lb per sq in.

A = $(634.0 - 620) \times 7.86 \times 10^{-6} \times 25.8 \times 10^6 - 0.30 \times 4292 = 1551$ lb per sq in.

B = $(676.5 - 620) \times 7.97 \times 10^{-6} \times 25.3 \times 10^6 + 0.30 \times 4292 = 12{,}575$ lb per sq in.

s_3 = $1943 + 0.237A + 0.264B = 5630$ lb per sq in.

s_1 = $1550 - 5630 = -4079$ lb per sq in.

s_2 = $12{,}575 - 5630 = 6945$ lb per sq in.

From the manner in which the above equations were derived, s_3 is a tensile stress and s_1 and s_2 are compressive stresses when preceded by a plus sign. The fact that s_1 works out with a negative sign shows that it is a tensile stress.

The distribution of the axial stresses in the tube before bending is shown in Fig. 18 for the heat-absorption rate of 30,000 Btu per hr per sq ft. The figure represents a longitudinal section through the tube with the furnace on the right-hand side. Tensile stresses have been plotted above the zero line

and compressive stresses below. On the furnace side, the axial stress in the tube wall varies from a compressive stress of s_2 = 6945 lb per sq in. at the outside surface to a tensile stress of s_1 = 4079 lb per sq in. at the inside surface. These axial stresses extend half-way around the tube as indicated by the horizontal lines at s_1 and s_2. On the opposite side of the tube, the tensile stress is s_3 = 5630 lb per sq in. across the tube wall and around one-half of the tube as indicated by the horizontal line s_3.

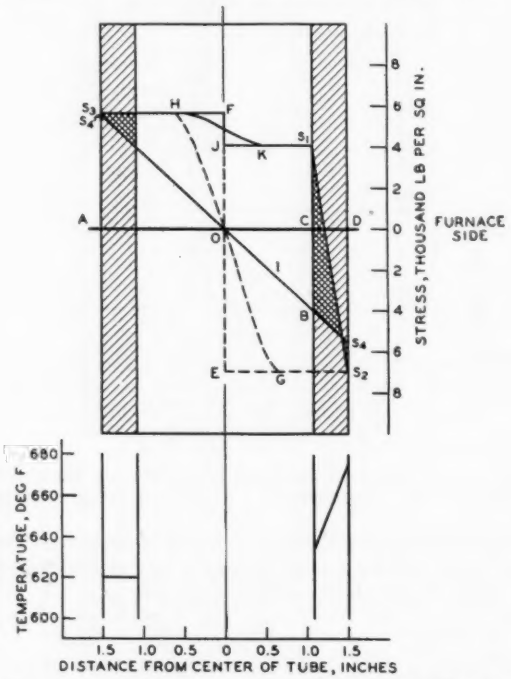

FIG. 19 AXIAL STRESSES IN TUBE WALL AFTER BENDING FOR NON-UNIFORM HEAT ABSORPTION OF 30,000 BTU PER HR PER SQ FT

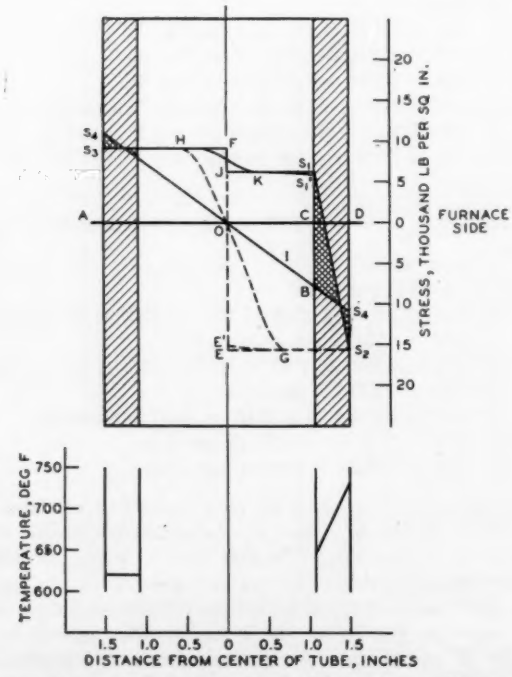

FIG. 20 AXIAL STRESSES IN TUBE WALL AFTER BENDING FOR NON-UNIFORM HEAT ABSORPTION OF 60,000 BTU PER HR PER SQ FT

The axial stresses before bending are shown for heat-absorption rates of 60,000 and 90,000 lb per sq in. by similar lines in Figs. 20 and 21. These figures have additional lines on them to show the modifications in these axial stresses due to bending of the tube, which will now be discussed.

AXIAL STRESSES AFTER BENDING IN A THICK BOILER TUBE HEATED ON ONE SIDE ONLY

That the stresses induced in a boiler tube by being heated on one side only tend to bend the tube convex toward the furnace is indicated in Fig. 18 by the moments of the stresses there shown being clockwise on both the furnace and the opposite sides. As the tube bends, the moments of these stresses will be reduced; and bending will cease when the moments of the stresses remaining are reduced to zero. As the tube bends, the axial stresses are relieved in proportion to their distances from the neutral axis of the tube cross-section. That is, bending is equivalent to superimposing upon the original stresses additional stresses varying from zero at the neutral axis to a maximum at the outermost fiber as represented by the line s_4s_4 in Fig. 19. If not restrained, the tube will bend to a curvature where the moments

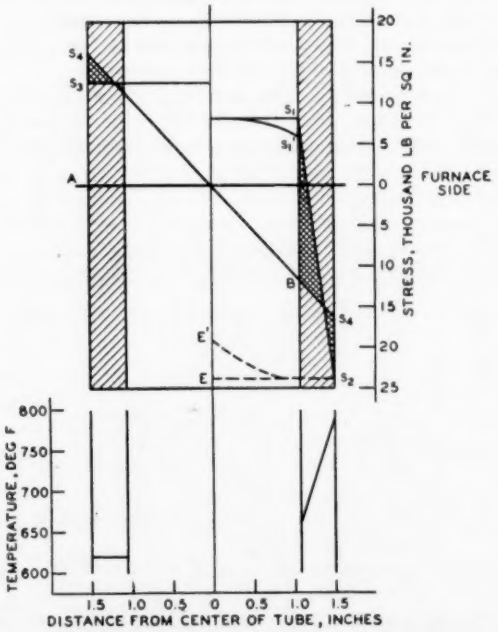

FIG. 21 AXIAL STRESSES IN TUBE WALL AFTER BENDING FOR NON-UNIFORM HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

of these superimposed stresses just balance the moments of the original stresses calculated for the tube before bending as previously explained.

The formulas derived in Appendix No. 1 for calculating the maximum stress at the outermost fiber superimposed by bending of an unrestrained tube upon the stresses before bending are as follows:

$$s_4 = \frac{4(M_1 + M_2)r_2}{\pi(r_2^4 - r_1^4)}$$

$$M_1 = 2\left[\frac{s_1(r_2^3 - r_1^3)}{3} + \frac{(s_2 - s_1)(r_2^4 - r_1^4)}{4(r_2 - r_1)} - \frac{(s_2 - s_1)r_1(r_2^3 - r_1^3)}{3(r_2 - r_1)}\right]$$

$$M_2 = \frac{2s_3(r_2^3 - r_1^3)}{3}$$

where r_1 = inside radius of tube wall, inches
r_2 = outside radius of tube wall, inches
s_1 = axial compressive stress before bending at r_1 on furnace side, lb per sq in.
s_2 = axial compressive stress before bending at r_2 on furnace side, lb per sq in.
s_3 = axial tensile stress before bending in tube wall on opposite to furnace side, lb per sq in.

For a heat-absorption rate on the furnace side of 30,000 Btu per hr per sq ft, we have previously calculated s_1 = —4079 lb per sq in., s_2 = 6945 lb per sq in., and s_3 = 5630 lb per sq in. Substituting these values and r_1 = 1.075 in. and r_2 = 1.5 in.,

M_1 = 2890 lb-in.
M_2 = 8005 lb-in.
s_4 = 5584 lb per sq in.

This value of s_4 has been plotted in Fig. 19 as a reduction in the compressive stress at the outermost fiber on the furnace side of the tube and as a reduction in the tensile stress at the outermost fiber on the opposite side of the tube. The straight line s_4s_4 represents the reductions in stress at all points in the tube wall and therefore constitutes a new base line from which to measure the stresses remaining after bending from those calculated for conditions before bending.

Thus, at the middle point of the furnace side of the tube, the compressive stress at the outside surface has been reduced by bending from Ds_2 to s_4s_2. This compressive stress at the outside surface after bending gradually increases from s_4s_2 as we pass around the tube until it reaches the original value OE at the center line where heat absorption was assumed to decrease suddenly to zero. At the middle of the opposite side of the tube, the tensile stress at the outside surface has been reduced by bending from As_2 to s_4s_2. This tensile stress at the outside surface after bending gradually increases from s_4s_2 as we pass around the tube until it reaches the original value OF at the center line where heat absorption was assumed to start suddenly. The stresses at the inside surface of the tube wall can be traced in a similar manner. The increase due to bending in tensile stress at the inside surface on the furnace side of the tube from Cs_1 to Bs_1 may be noticed. The stress gradients through the tube wall for the extreme front and rear portions of the tube are shown by the double cross-sectioning in Fig. 19. The stress gradient will evidently be different in each portion of the wall.

Actually, the heat-absorption rate will not remain the same on the furnace side of the tube up to the center line and then suddenly cease. Heat absorption may remain practically constant over a portion of the area exposed to the furnace, but it will gradually change from this value to zero or to a relatively low rate over the rear portion of the tube. Consequently, the stress before bending will not change suddenly as indicated in Fig. 19 from E to F at the center line of the tube, but will change more gradually along some line such as GH. At the inside surface, there will be a gradual change KH rather than the abrupt change JF. The maximum compressive stress at the outside surface after unrestrained bending will therefore be IG instead of OE.

All stresses in Fig. 19 for a heat-absorption rate of 30,000 Btu per hr per sq ft are within the proportional limit of mild steel. For the higher heat-absorption rate of 60,000 Btu per hr per sq ft, however, some of the stresses shown in Fig. 20 are above the proportional limit and should be reduced in the manner previously explained for circumferential stresses. This has been done, the lines $E'G$ and $s_1'K$ showing the stresses as reduced from EG and s_1K, respectively. These stress reductions upset the balance between the axial stresses in the tube wall and the internal fluid pressure, but the unbalance is so small that no change in the zero line is necessary and the stresses shown in Fig. 20 may be taken as representative of the axial stresses when one side only of the tube absorbs heat at the rate of 60,000 Btu per hr per sq ft.

When the rate of heat absorption is increased to 90,000 Btu per hr per sq ft, the axial stresses at some points in the tube wall shown in Fig. 21 are above the creep limit of the material as well as above the proportional limit. If the stresses at these points are reduced to the creep limit, the stresses at other points in the tube wall must be increased to balance the internal fluid pressure as previously explained for circumferential stresses. In order to make this adjustment, it was necessary to divide the furnace side of the tube wall radially into 32 sections and plot the stress gradient for each of the 16 pairs of similar sections on either side of the center. It was unnecessary to do this for the opposite side of the tube where the stresses are all within the creep limit and but slightly exceed the proportional limit at some points. The final result is shown in Fig. 22 with the new zero line. It may be mentioned that before reducing the stresses to the creep limit, the probable shift in the zero line was first estimated in order that a second reduction to the creep limit would not be necessary after the new zero line was determined.

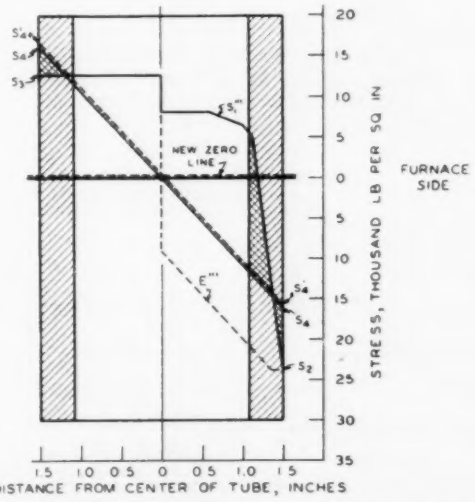

FIG. 22 AXIAL STRESSES IN TUBE WALL AFTER CREEP FOR NON-UNIFORM HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

RESIDUAL AXIAL STRESSES IN A THICK BOILER TUBE HEATED ON ONE SIDE ONLY

When heat transfer ceases and the internal pressure is reduced to zero, the boiler tube will tend to return to its original length. The portions which have not been stressed beyond the elastic limit will return very nearly to their original lengths and the residual stresses therein will be nearly zero. But in the portions of the tube wall where a permanent set has occurred due to plastic flow, the stresses will be reversed and high residual stresses may be produced. For a heat-absorption rate of 30,000 Btu per hr per sq ft there will be no residual axial stresses because the elastic limit of the material was not exceeded. For an absorption rate of 60,000 Btu per hr per sq ft there will be some residual axial stresses but these will be relatively small. For 90,000 Btu per hr per sq ft, however, the residual axial stresses are comparatively large. This case only will be given here.

The residual axial stresses for a heat absorption rate of 90,000 Btu per hr per sq ft on one side only of the tube were calculated in the same manner as previously explained for circumferential stresses. It was necessary to determine the residual stress for

each of the 32 sections into which the furnace side of the tube was divided from the stress gradient for each pair of sections, and then adjust the zero line for each section so as to balance the axial stresses over the whole cross-section of the tube wall with the total axial internal fluid pressure. The residual axial stresses at the inner and outer surfaces of the tube wall are plotted in Fig. 23 and Fig. 24, respectively.

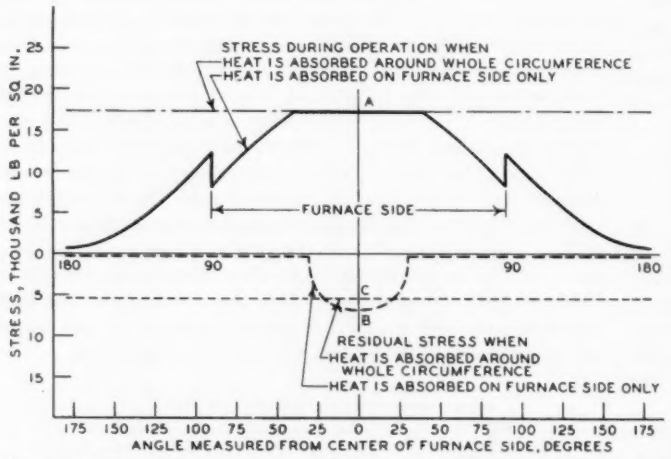

FIG. 23 DEVELOPMENT OF AXIAL STRESS AT INNER SURFACE OF TUBE WALL FOR NON-UNIFORM HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

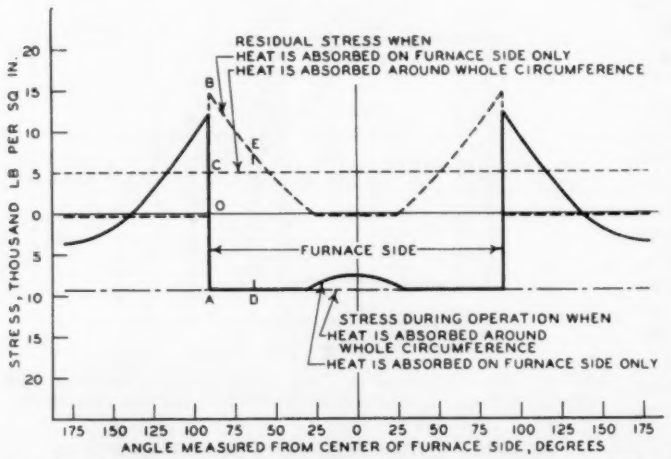

FIG. 24 DEVELOPMENT OF AXIAL STRESS AT OUTER SURFACE OF TUBE WALL FOR NON-UNIFORM HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT

COMPARISON OF AXIAL STRESSES IN A THICK BOILER TUBE HEATED ON ONE SIDE ONLY WITH THOSE FOR UNIFORM HEAT ABSORPTION

The maximum stresses in a boiler tube always occur at the inner and outer surfaces of the tube wall. Therefore plots of the stresses on developments of the inner and outer circumferences of the tube wall will show the maximum stresses in the tube. The axial stresses for the boiler tube heated on one side only are so plotted in Figs. 23 and 24 in comparison with the axial stresses for uniform heat absorption around the tube circumference.

Referring to Fig. 23, it is seen that when the tube is heated on one side only, the maximum axial stress occurs at the center of the furnace side. At this point the tensile stress during operation is 17,300 lb per sq in. and the residual compressive stress is 6900 lb per sq in., making a stress range of 24,200 lb per sq in. as shown by the distance AB. The distance AC shows that if the tube is heated uniformly around its circumference, the stress range is 22,800 lb per sq in. from a working tensile stress of 17,300 lb per sq in. to a residual compressive stress of 5500 lb per sq in. The working tensile stress is the same in both cases because this stress was assumed in both cases to reach the creep-limit stress of 17,300 lb per sq in. corresponding to the temperature of 662 F at the inner surface of the tube wall on the furnace side. When the tensile stress during operation tends to go much above the creep limit, the residual compressive stress will be correspondingly large. Therefore the stress range is a criterion of the stress conditions in the tube wall rather than the stress during operation only, and the metal would fail by reason of repeated reversals of stress rather than by simple tension or compression.

Referring to Fig. 24, at the outer surface of the tube, the maximum stress range for uniform heat absorption is AC = 14,400 lb per sq in. from a working compressive stress of 9400 lb per sq in. to a residual tensile stress of 5000 lb per sq in. For heat absorption on one side only, the maximum stress range is AB = 24,000 lb per sq in. from the same working compressive stress of 9400 lb per sq in. to a residual tensile stress of 14,600 lb per sq in. This stress range occurs at the point where the rate of heat transfer was assumed to decrease abruptly from 90,000 Btu per hr per sq ft to zero. As in practice the rate of heat transfer will occur gradually rather than abruptly, the maximum stress range for non-uniform heating will be less than 24,000 lb per sq in. The maximum stress range will occur where the rate of heat transfer begins to fall off as we pass around the tube from the furnace side. If this point is 65 deg from the middle point of the furnace side rather than 90 deg as above assumed, the maximum stress range will be reduced to 16,600 lb per sq in. As heat absorption becomes more nearly uniform around the circumference of the tube the maximum stress range at the outer surface of the tube wall will continue to decrease and will approach as a limit the stress range for uniform heat absorption.

When the heat absorption falls off gradually around the tube rather than abruptly, the moments of the resultant stresses about the vertical axis before bending will be less than previously calculated, thereby reducing the stress s_4 in Fig. 22. This will decrease the maximum stress range at the inner surface of the tube wall represented in Fig. 23. As the heat absorption becomes more nearly uniform, the maximum stress range AB will decrease and approach as a limit the stress range AC for uniform heat absorption.

FATIGUE STRENGTH OF THICK BOILER TUBES

That the mere stressing of a boiler tube beyond the elastic limit of the material near the inner and outer surfaces of the tube wall is not injurious to the tube becomes evident when we consider that stressing beyond the elastic limit is done purposely in many manufacturing operations of rolling, drawing, and spinning in order to improve the material by raising its elastic limit and ultimate strength. It is well known, for example, that cold-drawn wire has a higher elastic limit and a greater tensile strength than the ingot from which it was made. Helical steel springs are purposely overloaded in order to stress a portion of the material beyond the elastic limit and give it a permanent set so that the springs will thereafter bear a greater load without permanent deflection and without failure by fatigue than they would if they had not been so overloaded. In boiler

tubes subjected to high rates of heat absorption, this improvement in the material is automatically accomplished by the conditions of service rather than requiring a separate manufacturing operation to accomplish it.

Referring to Fig. 4, the portion of the mild steel in the tube wall which has been loaded beyond the elastic limit to the point H', now follows the line $H'J$ when the load is released. This portion of the material now has an elastic limit H' higher than the original elastic limit at G, and so long as the working stress does not exceed H', there will be elastic deformation of the material in proportion to the stress along the line IH'. Due to the permanent set acquired by certain portions of the tube wall being stressed beyond the elastic limit to H' and to other portions of the tube wall not being stressed beyond the elastic limit G, the stress in these certain portions will be reversed when heat transfer ceases and the internal fluid pressure is reduced to zero.

At the inner surface of the tube wall, the circumferential stress varies from 20,000 lb per sq in. tension to 6300 lb per sq in. compression before creep has occurred, and from 17,400 lb per sq in. tension to 9000 lb per sq in. compression after creep has occurred to the creep-limit stress for a heat-absorption rate of 90,000 Btu per hr per sq ft. These two ranges of circumferential stress variation are compared in Fig. 25 with test data on the stress ranges which may be repeated ten million times without failure of mild steel as explained in Appendix No. 2.

A similar comparison is made in Fig. 26 for the ranges in axial stress variation due to both uniform and non-uniform heat absorption around the tube at a rate of 90,000 Btu per hr per sq ft. With uniform heat absorption, the stress range at the inner surface of the tube wall is from 17,300 lb per sq in. tension to 5500 lb per sq in. compression, and the stress range at the outer surface of the tube wall is from 5000 lb per sq in. tension to 9400 lb per sq in. compression. When the heat absorption is non-uniform, the maximum possible ranges theoretically occur when the heat absorption is assumed to change abruptly from 90,000 Btu per hr per sq ft to zero, and these ranges are: On the inner surface of the tube wall, 17,300 lb per sq in. tension to 6900 lb per sq in. compression; on the outer surface of the tube wall, 14,600 lb per sq in. tension to 9400 lb per sq in. compression. Actually, these latter ranges will approach the former ranges with a gradual change in the rate of heat absorption around the tube.

By reference to Figs. 25 and 26, it is seen that the maximum stress ranges in a thick boiler tube subjected to a very high rate of heat absorption are all within ranges withstood ten million times without failure during test. If the boiler tube passed through one cycle per day, it would require

27,400 years to complete	10,000,000 cycles
2,740 years to complete	1,000,000 cycles
274 years to complete	100,000 cycles

Thus, even if at this slow rate of reversal, the number of reversals permissible should be much less than that found by test with a rapid rate of stress reversal, boiler tubes should last many years so far as any stresses due to a high rate of heat absorption are concerned.

Bursting of Thick Boiler Tubes by Internal Pressure

The foregoing discussion has shown that a boiler tube will not fail within any reasonable period of time by fatigue due to repeated reversals of the stresses set up by high rates of heat absorption either uniformly or non-uniformly disposed around the tube circumference. Before the tube can fail by bursting, all portions of the tube wall must be stressed to a point where more or less rapid creep will occur to rupture. Before this can take place, all heat-transfer stresses will be entirely neutralized by creep. Failure of the tube will then be caused by the stresses due to internal fluid pressure only. These facts may be shown by reference to Figs. 27, 28, and 29.

While the boiler tube in Figs. 27, 28, and 29 is of the same dimensions as in the previous discussion, the steam pressure is

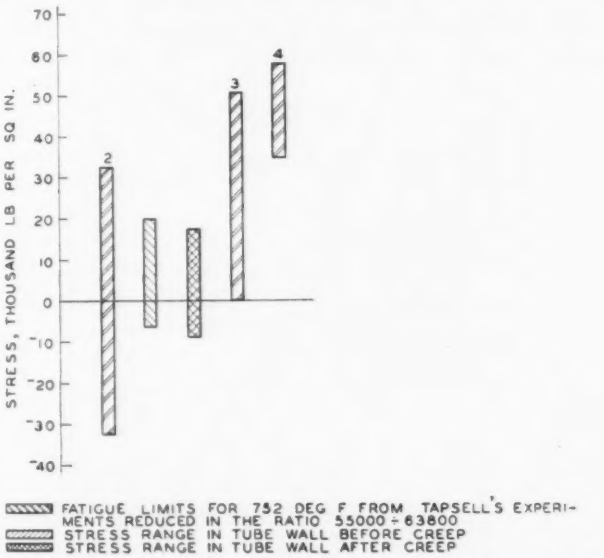

Fig. 25 Comparison of Circumferential-Stress Ranges for Heat Absorption of 90,000 Btu per Hr per Sq Ft With Fatigue-Test Data

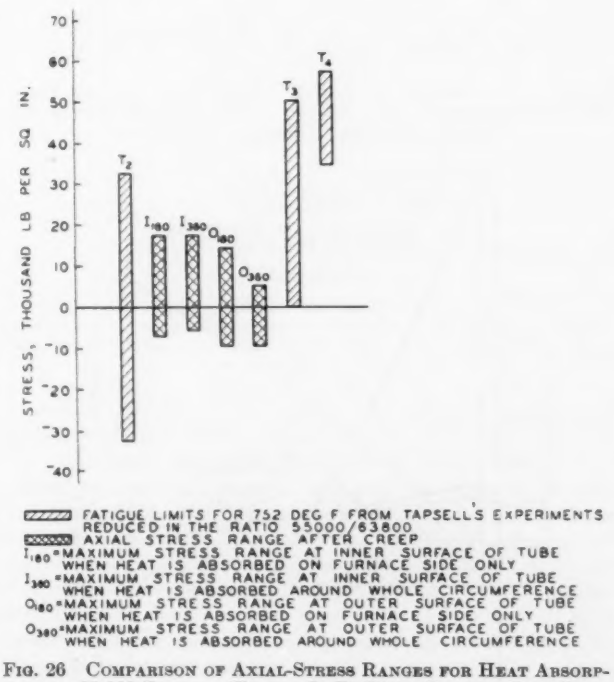

Fig. 26 Comparison of Axial-Stress Ranges for Heat Absorption of 90,000 Btu per Hr per Sq Ft With Fatigue-Test Data

1390 lb gage instead of 1840 lb gage for the reason that these figures were originally made for a study of a different installation than the preceding figures. The circumferential stresses only have been considered because, as shown previously, the axial stresses are less than the circumferential stresses except with an abnormally non-uniform heat absorption around the tube.

Referring to Figs. 27, 28, and 29, the difference of the areas

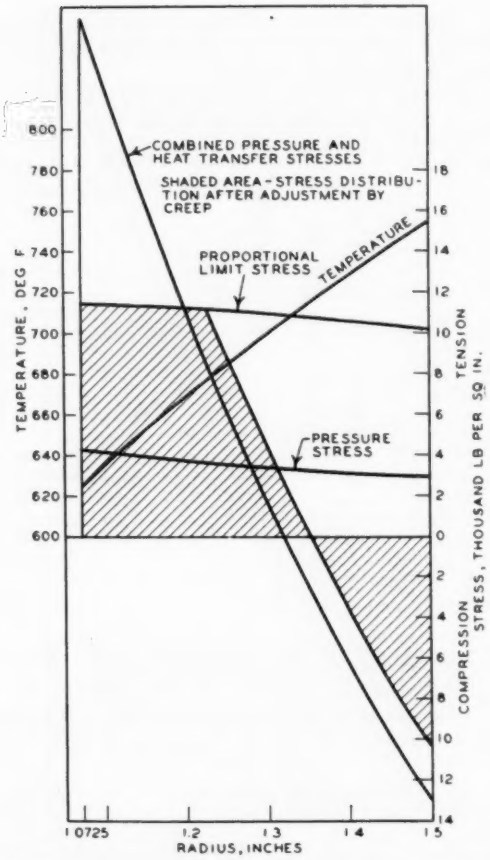

FIG. 27 CIRCUMFERENTIAL STRESS DISTRIBUTION IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT WITH 41.9 F TEMPERATURE DROP THROUGH WATER FILM

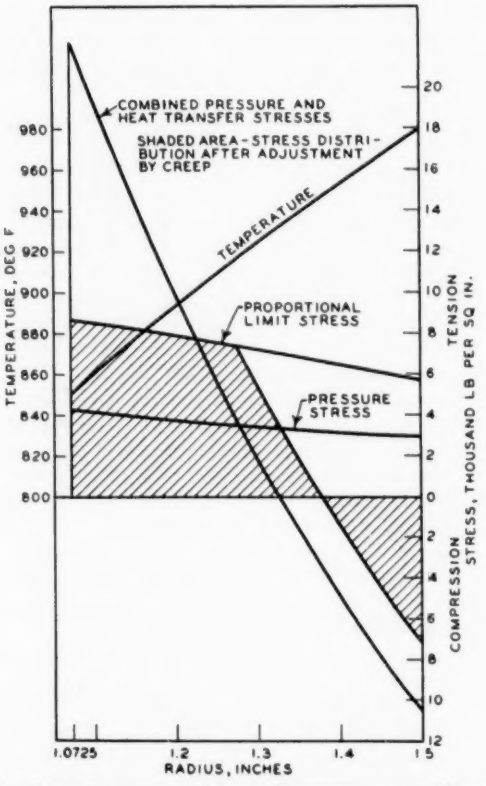

FIG. 28 CIRCUMFERENTIAL STRESS DISTRIBUTION IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT WITH 224.6 F TEMPERATURE DROP THROUGH WATER FILM

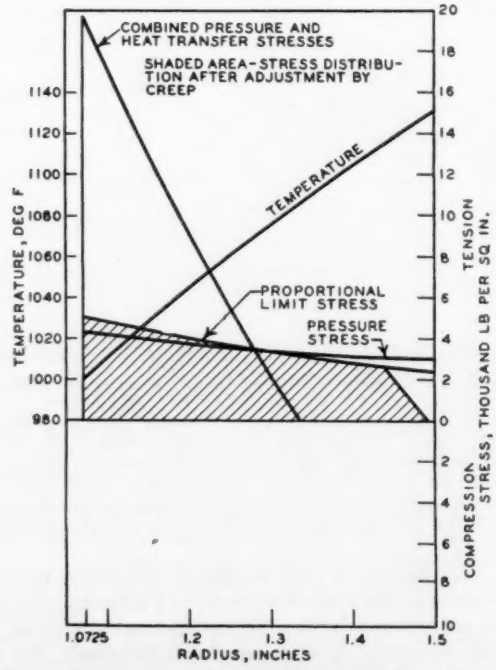

FIG. 29 CIRCUMFERENTIAL STRESS DISTRIBUTION IN TUBE WALL FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT WITH 374.6 F TEMPERATURE DROP THROUGH WATER FILM

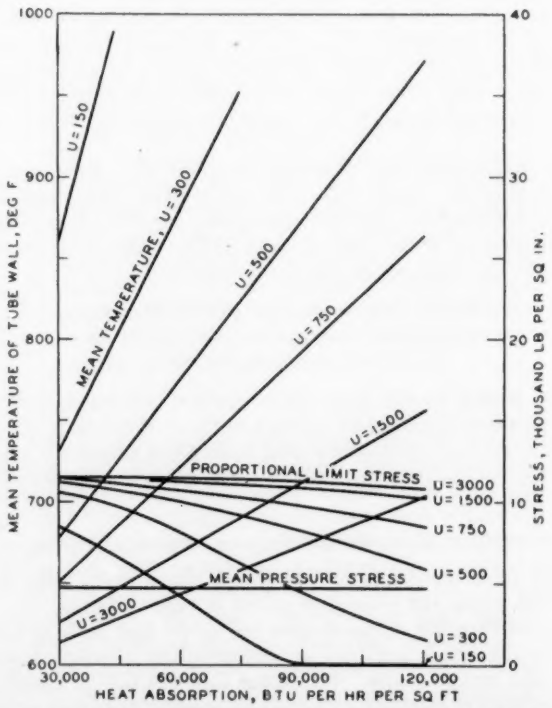

FIG. 30 VARIATION OF MEAN TEMPERATURE AND CORRESPONDING PROPORTIONAL-LIMIT STRESS WITH HEAT ABSORPTION IN A 3-IN. MILD-STEEL TUBE WITH WALL 0.344 IN. THICK

above and below the zero line to the curve for combined pressure and heat-transfer stresses must equal the area under the line for pressure stress only in accordance with the relations previously explained, these stress lines being calculated in accordance with the theory of elasticity of materials. Due, however, to the maximum values of these calculated stresses being above the elastic limit of the material, plastic flow will occur to reduce these stresses to much lower values, as previously explained. Eventually, these stresses will all be reduced to the creep-limit stress at the operating temperature at each point in the tube wall. A comparison of Figs. 36 and 39 in Appendix No. 2 shows that at low temperatures the creep-limit stress is above the proportional-limit stress of mild steel, while at high temperatures the reverse is true. For the purpose of this discussion, the proportional-limit stress has been taken as the stress to which all higher stresses are eventually reduced by plastic flow.

Curves representing the proportional-limit stress of mild steel at the varying temperature in the tube wall were drawn above and below the zero line to represent the limiting stresses in the tube wall. Wherever the calculated stress exceeded the proportional-limit stress it was reduced to that limiting value;

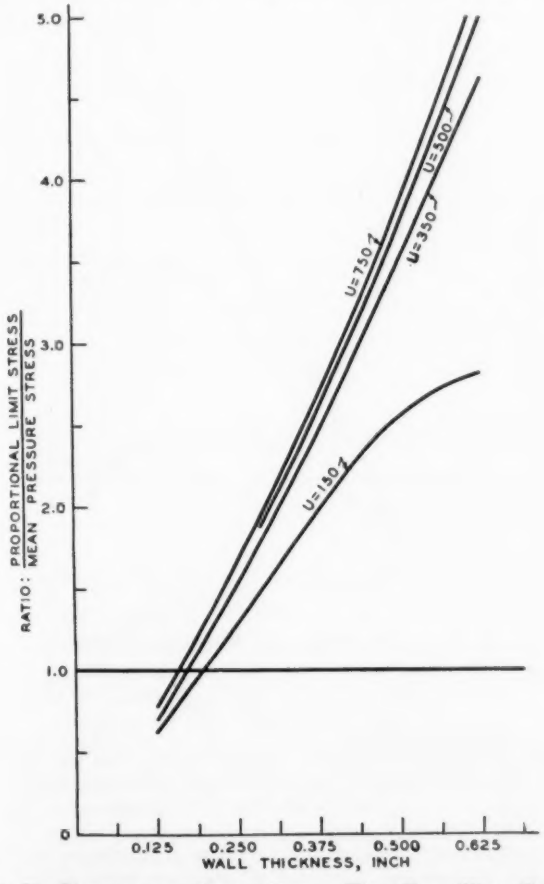

FIG. 31 VARIATION OF SAFETY FACTOR WITH TUBE-WALL THICKNESS FOR HEAT ABSORPTION OF 30,000 BTU PER HR PER SQ FT WITH DIFFERENT COEFFICIENTS OF HEAT TRANSFER THROUGH WATER FILM

but to compensate for this reduction in stress adjacent to the inner surface of tube wall, the stresses at other points within the tube wall were increased. Compensation is evidently complete when the combined stress line is moved up until the difference of the cross-sectioned areas above and below the zero line just equals the area under the pressure-stress line.

The temperature and corresponding proportional-limit curves in Figs. 27, 28, and 29 were drawn for three different coefficients of heat transfer from the inner surface of the tube wall to the water-steam mixture within the tube with the same rate of heat absorption, 90,000 Btu per hr per sq ft. The effect of an increase in temperature drop through the water film from 41.9 F to 224.6 F and finally to 374.6 F is to move the proportional-limit-stress curve toward the pressure-stress curve. Under the final

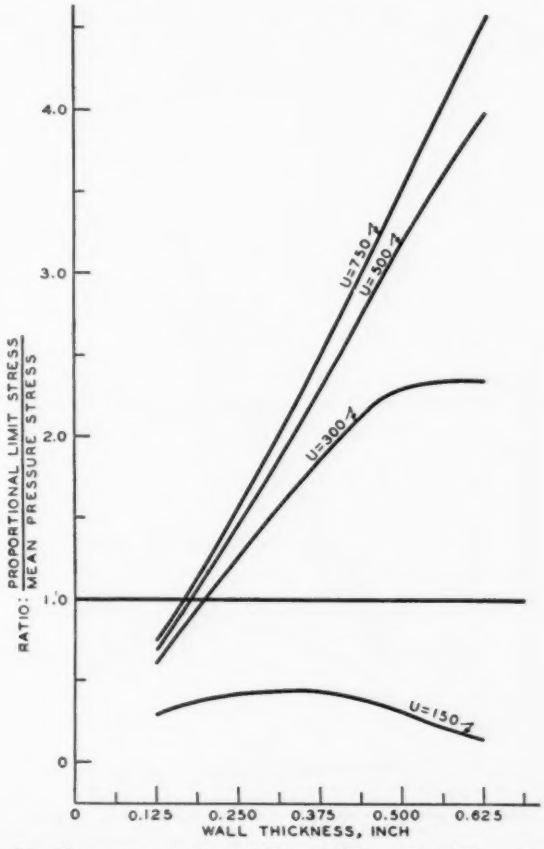

FIG. 32 VARIATION OF SAFETY FACTOR WITH TUBE-WALL THICKNESS FOR HEAT ABSORPTION OF 60,000 BTU PER HR PER SQ FT WITH DIFFERENT COEFFICIENTS OF HEAT TRANSFER THROUGH WATER FILM

condition, the tube is just about to fail because the tube-wall temperature has increased until the stress due to internal pressure exceeds the creep-limit stress of the material which is below the proportional-limit stress at these high temperatures. Before this condition has been reached, all heat-transfer stresses have evidently been neutralized by creep. A measure of safety of the boiler tube is the ratio of the proportional-limit stress (or creep-limit stress) of the material of the tube wall at the mean operating temperature to the mean stress due to internal fluid pressure. When this ratio equals unity, the tube is about to burst by its internal pressure.

SAFEST THICKNESS OF BOILER-TUBE WALL

In a thin-walled tube the stresses due to internal fluid pressure are high so that the ratio of the proportional-limit stress at the mean wall temperature to the mean-internal-pressure stress may be low and the tube unsafe. As the thickness is increased, the pressure stress is considerably decreased at first without much change in the proportional-limit stress. It is conceivable, however, that a large increase in thickness with a high rate of heat

transfer might cause the mean temperature of the tube wall to become so high that the safety of the tube would be decreased in spite of the decrease in internal-pressure stress. The safest thickness of tube wall is that thickness where the ratio of the proportional-limit stress to the internal-pressure stress is a maximum.

For a given tube material, the safest thickness will depend upon the coefficient of heat transfer from the inner surface of the tube wall to the water-steam mixture within the tube, as well as upon the rate of heat absorption. To determine how this safest thickness compares with that specified in the A.S.M.E. Boiler Code, calculations were made for wall thicknesses from $^1/_8$ in. to $^5/_8$ in. for a 3-in. outside-diameter mild-steel tube under an internal steam pressure of 1390 lb gage. Heat-absorption rates of 30,000, 60,000, 90,000, and 120,000 Btu per hr per sq ft and film coefficient of 3000, 1500, 750, 500, 300, and 150 Btu per hr per sq ft per deg F were assumed The thickness specified by the A.S.M.E. Boiler Code for an internal steam pressure of 1390 lb gage is 0.312 in.

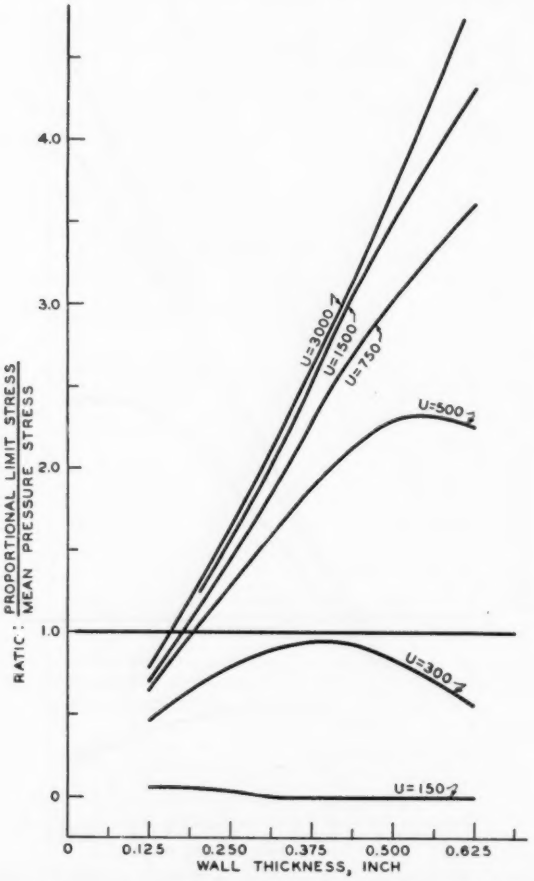

FIG. 33 VARIATION OF SAFETY FACTOR WITH TUBE-WALL THICKNESS FOR HEAT ABSORPTION OF 90,000 BTU PER HR PER SQ FT WITH DIFFERENT COEFFICIENTS OF HEAT TRANSFER THROUGH WATER FILM

For each tube-wall thickness, the mean wall temperature, corresponding proportional-limit stress, and mean-pressure stress were plotted as shown in Fig. 30 for a 0.344-in. wall. Then the ratio of proportional-limit stress to mean-pressure stress was plotted in Figs. 31–34, for the four assumed rates of heat absorption. In all cases the safest ratio is for a greater thickness of tube wall than specified by the A.S.M.E. Boiler Code. To make the tube thinner than called for would evidently be a step in the wrong direction.

The safety of a tube would be increased by using a material having a higher proportional-limit stress, such as a 0.45 per cent carbon steel instead of a 0.24 per cent as indicated by the proportional-limit curves in Fig. 36 of Appendix No. 2. Even with mild steel, however, the curves of Figs. 31–34 show that failure can occur only when the coefficient of heat transfer from the inner surface of the tube wall to the water-steam mixture within the tube is reduced to an abnormally low value by poor circulation within the tube or by scale accumulations on the tube wall unless the material is defective or corrosion occurs.

In closing, the author wishes to acknowledge the work of Messrs. R. H. Tilghman and G. H. Bierman, formerly members of the Technical Research Department of International Combustion Engineering Corporation, in preparing reports on various phases of the problem, data from these reports being utilized in the preparation of this paper.

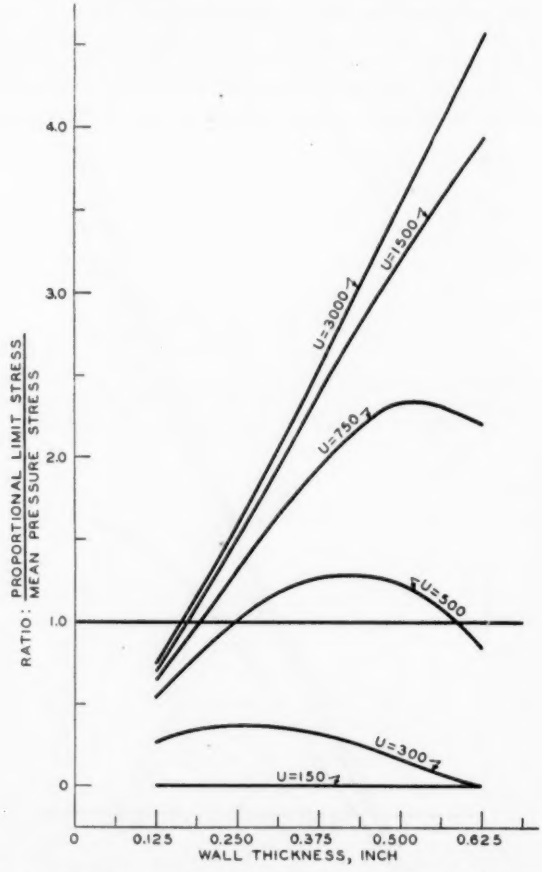

FIG. 34 VARIATION OF SAFETY FACTOR WITH TUBE-WALL THICKNESS FOR HEAT ABSORPTION OF 120,000 BTU PER HR PER SQ FT WITH DIFFERENT COEFFICIENTS OF HEAT TRANSFER THROUGH WATER FILM

Appendix No. 1

DERIVATION OF FORMULAS

TEMPERATURE DROP THROUGH CYLINDRICAL TUBE WALL

Consider a cylindrical tube in which heat is transferred radially through the tube wall to a fluid flowing within the tube. Let

r_1 = inside radius of tube wall, inches
r_2 = outside radius of tube wall, inches
T_1 = temperature at inside surface, deg F
T_2 = temperature at outside surface, deg F
Q = rate of heat absorption at outside surface, Btu per hr per sq ft
λ = thermal conductivity of material, Btu per hr per sq ft per deg F for 1 ft in thickness.

The heat absorbed by a 1-ft length of tube will be $2\pi r_2 Q/12$ Btu per hr. Let the temperature be T at a cylindrical annulus of radius r and thickness dr within the tube wall. The heat passing through a 1-ft length of this annulus will be $2\pi r\lambda dT/dr$ Btu per hr. Equating the two expressions for flow of heat,

$$2\pi r\lambda \frac{dT}{dr} = \frac{2\pi r_2 Q}{12} \quad \text{or} \quad dT = \frac{Qr_2}{12\lambda}\frac{dr}{r}$$

Integrating,

$$T = \frac{Qr_2}{12\lambda}\log_e r + C$$

Since $T = T_2$ when $r = r_2$,

$$C = T_2 - \frac{Qr_2}{12\lambda}\log_e r_2 \quad \text{and} \quad T = T_2 - \frac{Qr_2}{12\lambda}\log_e \frac{r_2}{r}$$

But $T = T_1$ when $r = r_1$, whence

$$C = T_1 - \frac{Qr_2}{12\lambda}\log_e r_1 \quad \text{and} \quad T = T_1 + \frac{Qr_2}{12\lambda}\log_e \frac{r}{r_1}$$

Eliminating $Qr_2/12\lambda$,

$$T = \frac{T_1 \log_e \frac{r_2}{r} + T_2 \log_e \frac{r}{r_1}}{\log_e \frac{r_2}{r_1}}$$

Equating the two expressions for T and solving for the temperature difference,

$$T_2 - T_1 = \frac{Qr_2}{12\lambda}\log_e \frac{r_2}{r_1}$$

Stresses in Cylindrical Tube Wall Due to Fluid Pressure

For the cylindrical tube, let

r_1 = inside radius of tube wall, inches
r_2 = outside radius of tube wall, inches
p_1 = internal fluid pressure, lb per sq in.
p_2 = external fluid press lb per sq in.

Then the radial compressive stress at the inside surface is p_1 lb per sq in. and at the outside surface is p_2 lb per sq in. Let p_1 be greater than p_2.

Consider a cylindrical annulus within the tube wall of radius r and thickness dr and let

p = radial compressive stress at radius r, lb per sq in.
t = circumferential tensile stress at radius r, lb per sq in.
s = axial tensile stress at radius r, lb per sq in.

The internal pressure acting on the cylindrical annulus is then p lb per sq in. Let the external pressure acting thereon be denoted by $p + dp$. Since the pressure difference tending to burst the cylindrical annulus is balanced by the circumferential stress therein, we have for unit length of annulus:

$$2pr - 2(p + dp)(r + dr) = 2tdr$$

Multiplying and neglecting products of small quantities,

$$pdr + rdp + tdr = 0$$

whence

$$t + p + r\frac{dp}{dr} = 0 \qquad [1]$$

Due to the greater internal pressure, let the circumferential length of the cylindrical annulus be increased $2\pi u$ inches. The tensile strain per unit length circumferentially will then be $2\pi u/2\pi r = u/r$. The strain radially will be du/dr. Let e be the tensile axial strain. Then for a coefficient of elasticity E and a Poisson's ratio $1/m$,

$$E\frac{du}{dr} = -p - \frac{1}{m}\left(t + s\right) \qquad [2]$$

$$E\frac{u}{r} = t - \frac{1}{m}\left(s - p\right) \qquad [3]$$

$$Ee = s - \frac{1}{m}\left(t - p\right) \qquad [4]$$

The radial stress p has been taken negative to represent compression in comparison with positive values of the circumferential tensile stress t and axial tensile stress s. From [3],

$$Eu = tr - \frac{sr}{m} + \frac{pr}{m}$$

Differentiating with respect to r,

$$E\frac{du}{dr} = t + r\frac{dt}{dr} - \frac{s}{m} - \frac{r}{m}\frac{ds}{dr} + \frac{p}{m} + \frac{r}{m}\frac{dp}{dr}$$

Subtracting from [2],

$$0 = -p - \frac{t}{m} - t - r\frac{dt}{dr} + \frac{r}{m}\frac{ds}{dr} - \frac{p}{m} - \frac{r}{m}\frac{dp}{dr} \qquad [5]$$

We shall assume that the axial strain e is uniform over the whole cross-section of the tube, which is evidently true for sections remote from the ends of the tube. Then, differentiating [4] with respect to r,

$$0 = \frac{ds}{dr} - \frac{1}{m}\frac{dt}{dr} + \frac{1}{m}\frac{dp}{dr} \qquad [6]$$

Substituting ds/dr from [6] in [5] and dividing through by $-[1 + (1/m)]$,

$$0 = p + t + \frac{r}{m}\frac{dp}{dr} + r\left(1 - \frac{1}{m}\right)\frac{dt}{dr}$$

Substituting $(p + t)$ from [1] and dividing through by $r[1 - (1/m)]$,

$$\frac{d}{dr}(t - p) = 0$$

Therefore

$$t - p = C, \text{ a constant} \qquad [7]$$

Subtracting [7] from [1],

$$2p + r\frac{dp}{dr} = -C$$

whence

$$\frac{1}{r}\frac{d}{dr}(r^2 p) = -C$$

or

$$d(r^2p) = -Crdr$$

Integrating,

$$r^2p = -C\frac{r^2}{2} + B$$

or

$$p = -\frac{C}{2} + \frac{B}{r^2} \quad \ldots\ldots [8]$$

Since $p = p_1$ at $r = r_1$ and $p = p_2$ at $r = r_2$, we get the values of the constants of integration,

$$C = \frac{2(r_1^2p_1 - r_2^2p_2)}{r_2^2 - r_1^2}$$

and

$$B = \frac{r_1^2r_2^2(p_1 - p_2)}{r_2^2 - r_1^2}$$

Substituting in [8], we have for the radial compressive stress

$$p = \frac{1}{r_2^2 - r_1^2}\left[r_2^2p_2 - r_1^2p_1 + \frac{r_1^2r_2^2}{r^2}\left(p_1 - p_2\right)\right] \ldots [9]$$

Substituting in [7], we have for the circumferential tensile stress

$$t = \frac{1}{r_2^2 - r_1^2}\left[r_1^2p_1 - r_2^2p_2 + \frac{r_1^2r_2^2}{r^2}\left(p_1 - p_2\right)\right] \ldots [10]$$

Since by [7], $(t - p)$ is constant if e is constant over the cross-section of the tube wall, we have from [4] that s is also constant over the cross-section of the tube wall. Hence

$$s = \frac{\pi r_1^2p_1 - \pi r_2^2p_2}{\pi r_2^2 - \pi r_1^2} = \frac{1}{r_2^2 - r_1^2}\left[r_1^2p_1 - r_2^2p_2\right] \ldots [11]$$

If p_2 is negligible in comparison with p_1, as when p_2 is atmospheric pressure and p_1 is a very high internal pressure, formulas [9], [10], and [11] reduce to

$$p = \frac{r_2^2 - r^2}{r_2^2 - r_1^2}\,\frac{r_1^2p_1}{r^2} \quad \ldots\ldots [12]$$

$$t = \frac{r_2^2 + r^2}{r_2^2 - r_1^2}\,\frac{r_1^2p_1}{r^2} \quad \ldots\ldots [13]$$

$$s = \frac{r_1^2p_1}{r_2^2 - r_1^2} \quad \ldots\ldots [14]$$

Stresses in Cylindrical Tube Wall Due to Fluid Pressure and to Heat Transfer Through Tube Wall

As before, let

r_1 = inside radius of tube wall, inches
r_2 = outside radius of tube wall, inches
p_1 = internal fluid pressure, lb per sq in.
p_2 = external fluid pressure, lb per sq in.
T_1 = temperature at inside surface, deg F
T_2 = temperature at outside surface, deg F, these temperatures being measured above some reference temperature T_0.

Consider a cylindrical annulus of radius r and thickness dr within the tube wall where the temperature is T deg F above the reference temperature T_0. Let

p = radial compressive stress at radius r, lb per sq in.
t = circumferential tensile stress at radius r, lb per sq in.
s = axial tensile stress at radius r, lb per sq in.

Then as previously derived,

$$t + p + r\frac{dp}{dr} = 0 \quad \ldots\ldots [1]$$

If α = coefficient of linear expansion per deg F, the strain due to the temperature rise T is αT. If the total strains are du/dr, u/r, and e in the radial, circumferential, and axial directions, respectively,

$$E\left(\frac{du}{dr} - \alpha T\right) = -p - \frac{1}{m}\left(t + s\right) \quad \ldots\ldots [2]$$

$$E\left(\frac{u}{r} - \alpha T\right) = t - \frac{1}{m}\left(s - p\right) \quad \ldots\ldots [3]$$

$$E(e - \alpha T) = s - \frac{1}{m}\left(t - p\right) \quad \ldots\ldots [4]$$

From [3],

$$Eu = E\alpha Tr + tr - \frac{sr}{m} + \frac{pr}{m}$$

Differentiating with respect to r,

$$E\frac{du}{dr} = E\alpha T + E\alpha r\frac{dT}{dr} + t + r\frac{dt}{dr} - \frac{s}{m} - \frac{r}{m}\frac{ds}{dr} + \frac{p}{m} + \frac{r}{m}\frac{dp}{dr}$$

Subtracting from [1],

$$0 = -p - \frac{t}{m} - E\alpha r\frac{dT}{dr} - t - r\frac{dt}{dr} + \frac{r}{m}\frac{ds}{dr} - \frac{p}{m} - \frac{r}{m}\frac{dp}{dr} \quad [5]$$

Assuming the axial strain e to be uniform over the whole cross-section, we have by differentiating [4],

$$\frac{ds}{dr} = -E\alpha\frac{dT}{dr} + \frac{1}{m}\frac{dt}{dr} - \frac{1}{m}\frac{dp}{dr} \quad \ldots\ldots [6]$$

Substituting ds/dr from [6] in [5] and dividing through by $-[1 + (1/m)]$,

$$0 = p + t + E\alpha r\frac{dT}{dr} + \frac{r}{m}\frac{dp}{dr} + r\left(1 - \frac{1}{m}\right)\frac{dt}{dr}$$

Substituting $p + t$ from [1] and dividing by $r[1 - (1/m)]$,

$$\frac{d}{dr}\left(t - p\right) + \frac{E\alpha m}{m - 1}\frac{dT}{dr} = 0$$

Therefore

$$t - p + \frac{E\alpha m}{m - 1}T = C, \text{ a constant} \quad \ldots\ldots [7]$$

Subtracting [7] from [1],

$$2p + r\frac{dp}{dr} - \frac{E\alpha m}{m - 1}T = -C$$

or

$$\frac{1}{r}\frac{d}{dr}\left(r^2p\right) - \frac{E\alpha m}{m-1}T = -C \quad \ldots\ldots [8]$$

But

$$T = \frac{T_1 \log_e \frac{r_2}{r} + T_2 \log_e \frac{r}{r_1}}{\log_e \frac{r_2}{r_1}} \quad \ldots\ldots [9]$$

Substituting [9] in [8] and integrating,

$$r^2p - \frac{E\alpha m}{(m-1)\log_e \frac{r_2}{r_1}}\left[(T_1 \log_e r_2 - T_2 \log_e r_1)\frac{r^2}{2} + (T_2 - T_1)\left(\frac{\log_e r}{2} - \frac{1}{4}\right)r^2\right] = -\frac{Cr^2}{2} + B$$

Whence

$$r^2p - \frac{E\alpha m}{m-1}\left[\frac{r^2T}{2} - \frac{r^2(T_2 - T_1)}{4\log_e \frac{r_2}{r_1}}\right] = -\frac{Cr^2}{2} + B \ldots [10]$$

where B is a constant of integration. Since $p = p_1$, and $T = T_1$ when $r = r_1$, and since $p = p_2$ and $T = T_2$ where $r = r_2$,

$$C = \frac{2(r_1^2p_1 - r_2^2p_2)}{r_2^2 - r_1^2} - \frac{E\alpha m}{m-1}\left[\frac{r_1^2T_1 - r_2^2T_2}{r_2^2 - r_1^2} + \frac{T_2 - T_1}{2\log_e \frac{r_2}{r_1}}\right] [11]$$

and

$$B = \frac{r_1^2r_2^2}{r_2^2 - r_1^2}\left[(p_1 - p_2) + \frac{E\alpha m}{m-1}\frac{T_2 - T_1}{2}\right] \ldots\ldots [12]$$

Substituting these constants in [10], the radial compressive stress is found to be

$$p = \frac{1}{r_2^2 - r_1^2}\left[r_2^2p_2 - r_1^2p_1 + \frac{r_1^2r_2^2}{r^2}\left(p_1 - p_2\right)\right] + \frac{E\alpha m}{2(m-1)}\left[\frac{r_1^2T_1 - r_2^2T_2}{r_2^2 - r_1^2} + \frac{r_1^2r_2^2}{r^2}\frac{T_2 - T_1}{r_2^2 - r_1^2} + T\right] \ldots [13]$$

Substituting the values of p and C in [7], the circumferential tensile stress is found to be

$$t = \frac{1}{r_2^2 - r_1^2}\left[r_1^2p_1 - r_2^2p_2 + \frac{r_1^2r_2^2}{r^2}\left(p_1 - p_2\right)\right] + \frac{E\alpha m}{2(m-1)}\left[\frac{r_2^2T_2 - r_1^2T_1}{r_2^2 - r_1^2} + \frac{r_1^2r_2^2}{r^2}\frac{T_2 - T_1}{r_2^2 - r_1^2} - \frac{T_2 - T_1}{\log_e \frac{r_2}{r_1}} - T\right] \ldots [14]$$

To find the axial tensile stress s, we utilize the relation

$$\int_{r_1}^{r_2} s \times 2\pi r dr = \pi r_1^2p_1 - \pi r_2^2p_2 \ldots\ldots [15]$$

From [4],

$$s = E(e - \alpha T) + \frac{1}{m}\left(t - p\right) \ldots\ldots [16]$$

The values of $(t - p)$ and C are obtained from [7] and [11], respectively. Whence

$$r_1^2p_1 - r_2^2p_2 = \int_{r_1}^{r_2} 2srdr$$

$$= \int_{r_1}^{r_2} 2\left[Ee - E\alpha T + \frac{1}{m}\left(t - p\right)\right]rdr$$

$$= \int_{r_1}^{r_2} 2\left[Ee - E\alpha T + \frac{1}{m}\left(C - \frac{E\alpha m}{m-1}T\right)\right]rdr$$

$$= \int_{r_1}^{r_2} 2\left[Ee - E\alpha T + \frac{2}{m}\frac{r_1^2p_1 - r_2^2p_2}{r_2^2 - r_1^2} - \frac{E\alpha}{m-1}\left(\frac{r_1^2T_1 - r_2^2T_2}{r_2^2 - r_1^2} + \frac{T_2 - T_1}{2\log_e \frac{r_2}{r_1}}\right) - \frac{E\alpha}{m-1} - T\right]rdr$$

Substituting T from [9] and integrating

$$Ee = \frac{m-2}{m}\frac{r_1^2p_1 - r_2^2p_2}{r_2^2 - r_1^2} - E\alpha\frac{r_1^2T_1 - r_2^2T_2}{r_2^2 - r_1^2} - E\alpha\frac{T_2 - T_1}{2\log_e \frac{r_2}{r_1}} \ldots\ldots [17]$$

Substituting in [16], we get for the axial tensile stress

$$s = \frac{r_1^2p_1 - r_2^2p_2}{r_2^2 - r_1^2} + \frac{E\alpha m}{m-1}\left[\frac{r_2^2T_2 - r_1^2T_1}{r_2^2 - r_1^2} - \frac{T_2 - T_1}{2\log_e \frac{r_2}{r_1}} - T\right] \ldots\ldots [18]$$

In order to eliminate T from expressions [13], [14], and [18], its value may be substituted from [9], thereby obtaining for the radial, circumferential, and axial stresses:

$$p = \left[-\frac{r_1^2p_1 - r_2^2p_2}{r_2^2 - r_1^2} + \frac{r_1^2r_2^2(p_1 - p_2)}{r^2(r_2^2 - r_1^2)}\right] + \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e \frac{r_2}{r_1}}\left[-(r_2^2\log_e r_2 - r_1^2\log_e r_1) + \frac{r_1^2r_2^2}{r^2}\log_e \frac{r_2}{r_1} + (r_2^2 - r_1^2)\log_e r\right] \ldots\ldots [19]$$

$$t = \left[\frac{r_1^2p_1 - r_2^2p_2}{r_2^2 - r_1^2} + \frac{r_1^2r_2^2(p_1 - p_2)}{r^2(r_2^2 - r_1^2)}\right] + \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e \frac{r_2}{r_1}}\left[(r_2^2\log_e r_2 - r_1^2\log_e r_1) - (r_2^2 - r_1^2) + \frac{r_1^2r_2^2}{r^2}\log_e \frac{r_2}{r_1} - (r_2^2 - r_1^2)\log_e r\right] \ldots\ldots [20]$$

$$s = \left[\frac{r_1^2p_1 - r_2^2p_2}{r_2^2 - r_1^2}\right] + \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e \frac{r_2}{r_1}}\left[2(r_2^2\log_e r_2 - r_1^2\log_e r_1) - (r_2^2 - r_1^2) - 2(r_2^2 - r_1^2)\log_e r\right] \ldots\ldots [21]$$

Stresses in Cylindrical Tube Wall Due to Heat Transfer Only Through Tube Wall

By a derivation similar to the preceding one, it may be shown that if

r_1 = inside radius of tube wall, inches
r_2 = outside radius of tube wall, inches
T_1 = temperature at inside surface, deg F, and
T_2 = temperature at outside surface, deg F, above some reference temperature T_0
p = radial compressive stress at radius r, lb per sq in.
t = circumferential tensile stress at radius r, lb per sq in.
s = axial tensile stress at radius r, lb per sq in.

$$p = \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e \frac{r_2}{r_1}}\left[-(r_2^2 \log_e r_2 - r_1^2 \log_e r_1) + \frac{r_1^2 r_2^2}{r^2}\log_e \frac{r_2}{r_1} + (r_2^2 - r_1^2)\log_e r\right] \quad [1]$$

$$t = \frac{E\alpha m(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e \frac{r_2}{r_1}}\left[(r_2^2 \log_e r_2 - r_1^2 \log_e r_1) - (r_2^2 - r_1^2) + \frac{r_1^2 r_2^2}{r^2}\log_e \frac{r_2}{r_1} - (r_2^2 - r_1^2)\log_e r\right] \quad [2]$$

$$s = \frac{E\alpha M(T_2 - T_1)}{2(m-1)(r_2^2 - r_1^2)\log_e \frac{r_2}{r_1}}\left[2(r_2^2 \log_e r_2 - r_1^2 \log_e r_1) - (r_2^2 - r_1^2) - 2(r_2^2 - r_1^2)\log_e r\right] \quad [3]$$

By comparing the expressions derived for fluid pressure only and for heat transfer only with the expressions derived for a combination of both effects, it will be seen that in each case the total stress is equal to the sum of the stresses due to fluid pressure and to heat transfer. Hence the stresses due to fluid pressure and to heat transfer may be calculated separately and then added to obtain the total stress in the tube wall. The complete derivation of the total stress has been included to show this fact. For the derivation of the formulas for heat transfer only, see the treatise on "Strength of Materials," by John Case.

Axial Stresses in Cylindrical Tube Wall Before Bending Due to Heat Transfer on One Side Only

Consider a cylindrical tube in which heat is transferred radially through the tube wall around 180 deg only of the circumference to a fluid flowing within the tube, the remaining 180 deg of the tube wall being at the same temperature as the fluid within. Let

r_1 = inside radius of tube wall, inches
r_2 = outside radius of tube wall, inches
p_1 = internal fluid pressure, lb per sq in. (outside fluid pressure being zero)
T_1 = temperature at inside surface of tube wall on furnace side, deg F
T_2 = temperature at outside surface of tube wall on furnace side, deg F
T_3 = temperature of tube wall on opposite to furnace side of tube, deg F
E_1 = modulus of elasticity corresponding to T_1, lb per sq in.
E_2 = modulus of elasticity corresponding to T_2, lb per sq in.
E = modulus of elasticity corresponding to $(T_1 + T_2)/2$, lb per sq in.
α_1 = coefficient of thermal expansion corresponding to T_1, inch per inch per deg F
α_2 = coefficient of thermal expansion corresponding to T_2, inch per inch per deg F
α = coefficient of thermal expansion corresponding to $(T_1 + T_2)/2$, inch per inch per deg F
$1/m$ = Poisson's ratio
s_1 = axial compressive stress at r_1 on furnace side, lb per sq in.
s_2 = axial compressive stress at r_2 on furnace side, lb per sq in.
s_3 = axial tensile stress in tube wall on opposite to furnace side, lb per sq in.

On the furnace side of the tube, the axial stress in the tube wall will vary from a maximum of s_2 lb per sq in. in compression at the outside surface to a minimum of s_1 lb per sq in. at the inside surface. The latter stress may be tension. This variation in stress is due primarily to heat transfer on the furnace side of the tube. On the opposite side there will be a nearly uniform axial tensile stress across the tube wall of s_3 lb per sq in. The summation of the compressive stresses on the furnace side of the tube is given by

$$\int_{r_1}^{r_2} s\pi r dr \quad [1]$$

where πr is the semicircumference of an elemental area at radius r. Assuming a straight-line relation for the stress in the tube wall between the stresses at the inside and outside surfaces,

$$\frac{s - s_1}{s_2 - s_1} = \frac{r - r_1}{r_2 - r_1} \quad [2]$$

Substituting s from [2] in [1] and integrating, we get for the summation of the stresses on the furnace side,

$$\frac{\pi}{6}(r_2 - r_1)\left[s_1(r_2 + 2r_1) + s_2(2r_2 + r_1)\right] \quad [3]$$

The summation over one-half of the cross-sectional area of the tube wall of the nearly constant stress s_3 in the wall on the opposite to the furnace side, is

$$\frac{\pi}{2} s_3(r_2^2 - r_1^2) \quad [4]$$

Since the summation of the axial tensile stresses will exceed the summation of the axial compressive stresses by the total axial internal pressure,

$$\pi r_1^2 p_1 = \frac{\pi}{2} s_3(r_2^2 - r_1^2) - \frac{\pi}{6}\left(r_2 - r_1\right)\left[s_1(r_2 + 2r_1) + s_2(2r_2 + r_1)\right] \quad [5]$$

In Equation [5] there are three unknown quantities, namely, s_1, s_2, and s_3. Let $s_1 + s_3 = A$ and $s_2 + s_3 = B$. Then, substituting $s_1 = A - s_3$ and $s_2 = B - s_3$ in [5] and solving for s_3,

$$s_3 = \frac{r_1^2 p_1}{r_2^2 - r_1^2} + \frac{A}{6}\frac{r_2 + 2r_1}{r_2 + r_1} + \frac{B}{6}\frac{2r_2 + r_1}{r_2 + r_1} \quad [6]$$

Now, A is the compressive stress at the inside surface and B is the compressive stress at the outside surface on the furnace side of the tube relative to the constant stress in the tube wall

on the opposite side of the tube due to the suppressed relative axial expansion of the different parts of the tube before bending. These relative expansions are due mainly to differences in temperature, but are also affected by the circumferential stresses in the tube wall. The radial stresses are so small as to be negligible. Hence we may write

$$A = (T_1 - T_3)\alpha_1 E_1 - \frac{t_1}{m} \quad [7]$$

and

$$B = (T_2 - T_3)\alpha_2 E_2 + \frac{t_2}{m} \quad [8]$$

The reason for the above expressions for A and B may be explained by considering a cube which is expanded equally in all directions by a rise in temperature. If a tensile stress t is applied in one direction, the expansion at right angles to this tensile stress will be reduced by an amount t/mE, where E is the modulus of elasticity of the material and $1/m$ is Poisson's ratio. Hence the compressive stress required to return the cube to its original length at right angles to the tensile stress is less than that corresponding to the temperature expansion by t/m. The circumferential stress t_1 at the inside surface is a tensile stress, while the circumferential stress t_2 at the outside surface is a compressive stress.

For the difference between the circumferential stresses at the outer and inner surfaces of the tube wall on the furnace side of the tube, the following approximate relation will be used, namely:

$$t_2 + t_1 = (T_2 - T_1)\alpha E$$

$$= 2t_1 = -2t_2$$

$$t_1 = (T_2 - T_1)\alpha E/2 \quad [9]$$

$$t_2 = -(T_2 - T_1)\alpha E/2 \quad [10]$$

These various relations were not combined, but were used separately to work out the several values.

Moments of Axial Stresses in Cylindrical Tube Wall Due to Heat Transfer on One Side Only

Consider a cylindrical tube in which for 180 deg of the circumference on the furnace side the stress varies in a straight-line relation from a maximum compressive stress in the outside surface to a minimum compressive stress at the inside surface while for the remaining 180 deg a constant tensile stress exists in the tube wall. Let

- r_1 = inside radius of tube wall, inches
- r_2 = outside radius of tube wall, inches
- s_1 = axial compressive stress before bending at r_1 on furnace side, lb per sq in.
- s_2 = axial compressive stress before bending at r_2 on furnace side, lb per sq in.
- s_3 = axial tensile stress before bending in tube wall on opposite to furnace side, lb per sq in.
- s_4 = axial stress in outermost fiber superimposed by bending, lb per sq in.

Let s be the stress on an elemental area $dr \times rd\theta$ distant r from the center of the tube cross-section. Then the elemental force is $srdrd\theta$ and the elemental moment about the neutral axis passing through the center of the tube cross-section is $r \sin \theta \times srdrd\theta$, where θ is the angle between the radius to the elemental area and the neutral axis. The total moment for one-half of the tube cross-section on one side of the neutral axis is

$$M = \int_{r=r_1}^{r=r_2} \int_{\theta=0}^{\theta=\pi} sr^2 \sin\theta \, drd\theta \quad [1]$$

On the furnace side of the tube,

$$s = s_1 + \left(s_2 - s_1\right)\frac{r - r_1}{r_2 - r_1} \quad [2]$$

as previously derived. Substituting in [1] and integrating, we get for the total moment of the stresses on the furnace side of the tube before bending:

$$M_1 = 2\left[\frac{s_1(r_2^3 - r_1^3)}{3} + \frac{(s_2 - s_1)(r_2^4 - r_1^4)}{4(r_2 - r_1)} - \frac{(s_2 - s_1)r_1(r_2^3 - r_1^3)}{3(r_2 - r_1)}\right] \quad [3]$$

For the opposite side of the tube, the stress

$$s = s_3 \text{ (constant)} \quad [4]$$

Substituting this in [1] and integrating, we get for the total moment of the stresses on the opposite to the furnace side of the tube before bending:

$$M_2 = \frac{2s_3(r_2^3 - r_1^3)}{3} \quad [5]$$

The stress superimposed on the tube at the outermost fiber by bending is given by the well-known relation

$$M = \frac{s_4 I}{c} \quad [6]$$

where $I = \frac{\pi}{4}(r_2^4 - r_1^4)$, section modulus, and $c = r_2$, distance from neutral axis to outermost fiber. If the tube is unrestrained, it will bend until

$$M = M_1 + M_2 \quad [7]$$

Hence

$$s_4 = \frac{4(M_1 + M_2)r_2}{\pi(r_2^4 - r_1^4)} \quad [8]$$

Appendix No. 2

PHYSICAL PROPERTIES OF MILD STEEL

When this investigation of the effects of heat absorption upon the stresses in boiler tubes was started, the best data available on the properties of mild steel at elevated temperatures were those by French, Cross, and Peterson in Technologic Paper No. 362 of the U. S. Bureau of Standards, entitled "Creep in Five Steels at Different Temperatures." The data on 0.24 per cent carbon steel in this publication checked very closely the data on 0.17 per cent carbon steel by Spring and Kanter in *Valve World* for August, 1928, in their article on "Long-Time or Flow Tests of Carbon Steels at Various Temperatures, With Particular Reference to Stresses Below the Proportional Limit." As stress-strain curves at several temperatures were given in the former publication but not in the latter, it was thought best to use the Bureau of Standards data almost exclusively in order to obtain a consistent group of physical properties.

For the modulus of elasticity of mild steel at elevated temperatures, the modified Sutherland formula was used as given

by Orrok in his paper on "High-Pressure Steam Boilers" in Trans. A.S.M.E. for 1928 (FSP-50-32). The curve representing this formula is given in Fig. 35 with points plotted for the experimental data on 0.24 per cent carbon steel from the Bureau of Standards publication. Although the points are somewhat scattered, it is believed that they justify the use of this formula in connection with the Bureau of Standards data.

The proportional limit of 0.24 per cent carbon steel is given by the curve in Fig. 36, plotted from data in the above-mentioned Bureau of Standards publication. There is also plotted in this figure a curve for 0.45 per cent carbon steel from data received from the U. S. Bureau of Standards.

In Figs. 37 and 38 are drawn the stress-strain diagrams used for correcting the calculated stresses in a thick boiler tube where the calculated stresses exceeded the elastic limit of mild steel. Fig. 37 contains the stress-strain diagrams for the mean wall temperatures with uniform heat absorption around the tube and also the experimental stress-strain diagrams from the Bureau of Standards publication. Fig. 38 contains the stress-strain diagrams for the mean tube-wall temperatures with non-uniform heat absorption. In constructing each of these stress-strain diagrams, a straight line was first drawn from the origin up to the proportional limit shown by the curve in Fig. 36 and at the slope given by the curve in Fig. 35 corresponding to the mean temperature of the tube wall. The portion of the curve above the proportional limit was then drawn to correspond with the experimental curves.

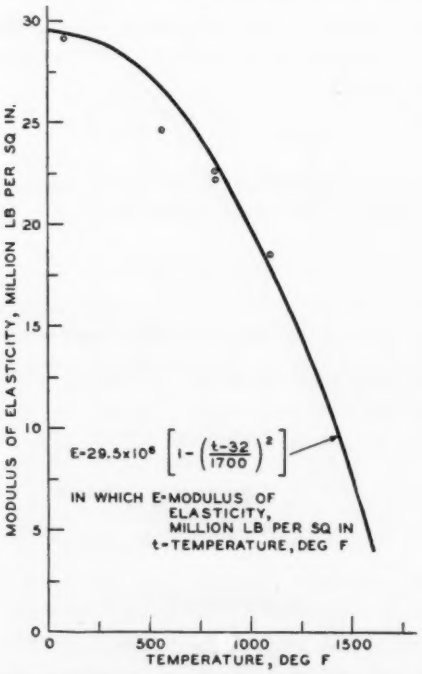

FIG. 35 MODULUS OF ELASTICITY OF MILD CARBON STEEL AT ELEVATED TEMPERATURES

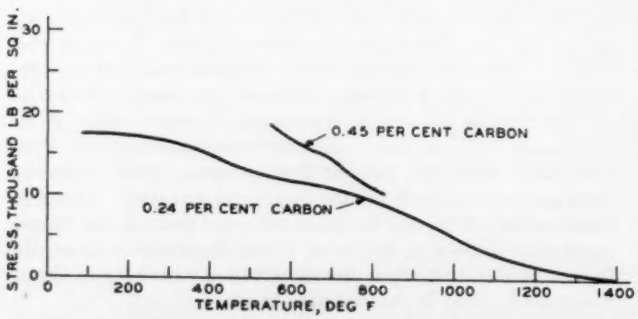

FIG. 36 PROPORTIONAL-LIMIT STRESS OF MILD AND MEDIUM CARBON STEEL AT ELEVATED TEMPERATURES

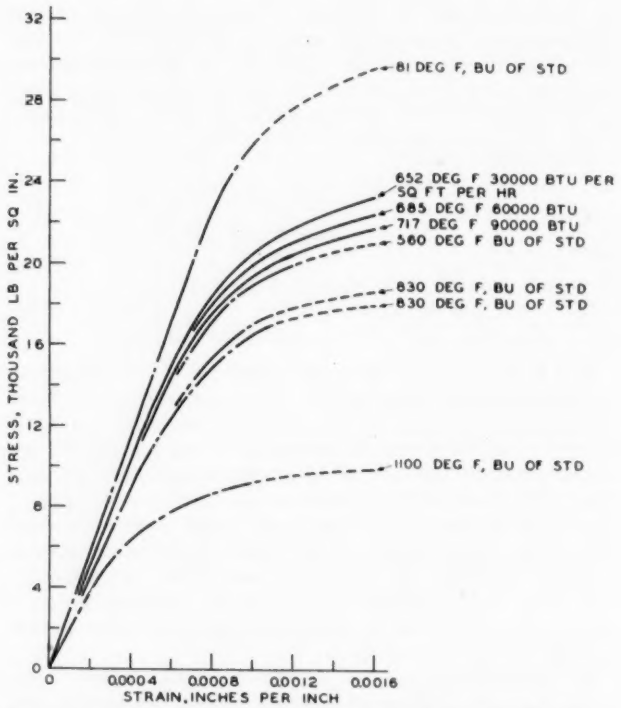

FIG. 37 STRESS-STRAIN DIAGRAMS FOR MILD CARBON STEEL AT MEAN TUBE-WALL TEMPERATURES FOR UNIFORM HEAT ABSORPTION

The curves in Fig. 39 for the rate of creep of 0.24 per cent carbon steel were obtained by cross-plotting the data in the Bureau of Standards publication where curves are given for three temperatures, 560, 830, and 1100 F.

The coefficient of thermal expansion of mild steel as given by the curve in Fig. 40 was based on an investigation made by R. H. Luebbers, formerly of the Technical Research Department of International Combustion Engineering Corporation.

The coefficient of thermal conductivity given in Fig. 41 was based on studies of Messrs. R. F. Nielsen and R. H. Luebbers, formerly of the Technical Research Department of International Combustion Engineering Corporation.

The value of Poisson's ratio was taken as 0.30.

The most comprehensive data found on the fatigue strength of mild steel at elevated temperatures were those in the paper by Tapsell published in the *Journal of the Iron and Steel Institute* for 1928, entitled "The Fatigue-Resisting Properties of 0.17 Per Cent Carbon Steel at Different Temperatures and at Different Mean Tensile Stresses." The steel was normalized and the experiments were conducted in a Haigh machine which gave direct pulsating stresses at the rate of 2400 cycles per min. The results of the experiments are given in Table 4. Failure did not occur during ten million stress cycles.

The fatigue limit was determined for three different stress ranges at each temperature. In column 2, the mean of the stress range was 0 lb per sq in.; for 70 F, the fatigue limit was reached when the stress was reversed from 28,000 lb per sq in. in tension to 28,000 lb per sq in. in compression. In column 3, the stress varied from zero to a maximum value in tension; for 70 F, the machine was set for a mean stress of 24,600 lb per sq in.

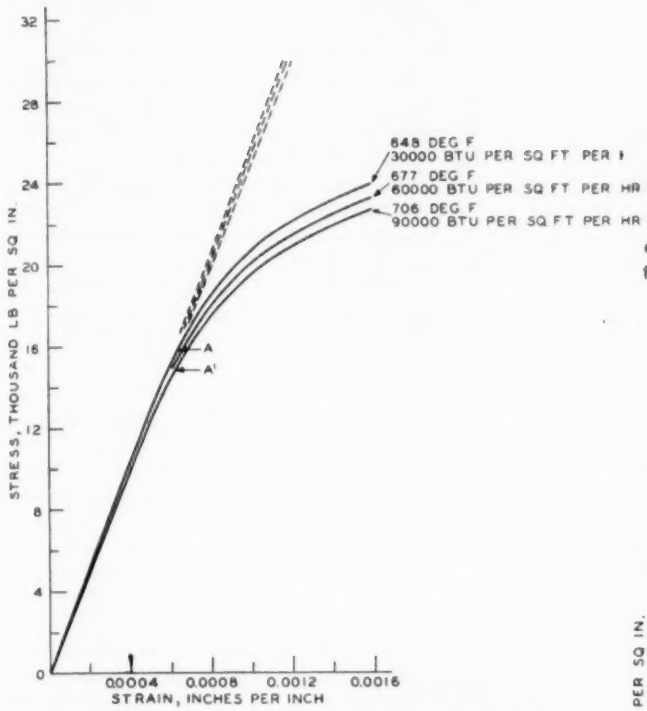

FIG. 38 STRESS-STRAIN DIAGRAMS FOR MILD CARBON STEEL AT MEAN TUBE-WALL TEMPERATURES FOR NON-UNIFORM HEAT ABSORPTION

and the stress varied 24,600 lb per sq in. above and below this mean value, that is, from 0 to 49,200 lb per sq in. in tension. Column 4 shows that at 70 F the machine was set for a mean stress of 49,300 lb per sq in. and the stress varied 16,800 lb per sq in. below and above this value, or from 32,500 to 66,100 lb per sq in. By comparison of columns 2, 3, and 4 with column 5, it is seen that, particularly at elevated temperatures, the fatigue strength of the material is above its proportional limit stress.

TABLE 4

Temperature, deg F	Fatigue-limit stress, 1000 lb per sq in.			Proportional limit, short-time test, 1000 lb. per sq in.	Tensile strength, short-time test, 1000 lb per sq in.
(1)	(2)	(3)	(4)	(5)	(6)
70	0 ± 28.0	24.6 ± 24.6	49.3 ± 16.8	35.8	63.8
212	0 ± 27.5	23.5 ± 23.5	47.1 ± 17.9	40.7	68.2
392	0 ± 27.5	25.8 ± 25.8	51.5 ± 24.6	30.2	84.2
572	0 ± 35.8	33.6 ± 33.6	67.2 ± 17.9	19.3	76.8
752	0 ± 37.6	29.1 ± 29.1	53.7 ± 13.4	14.6	62.2
932	0 ± 26.2	19.0 ± 19.0	31.3 ± 13.4	11.2	43.4

The proportional limits given by Tapsell, however, appear high when compared with the values in Fig. 36 from the experiments at the U. S. Bureau of Standards. The lower values obtained at the Bureau of Standards may be due to the extreme accuracy with which the proportional limit was determined at the first slight deviation of the stress-strain curve from a straight line. Usually, higher values of the proportional limit are obtained by reason of less accurate measurements.

It may be, however, that the material tested by Tapsell was superior to the average grade of mild steel, as is indicated by the high tensile strength in column 6. At 70 F, Tapsell obtained a tensile strength of 63,800 lb per sq in., while an average for ordinary mild steel would be 55,000 lb per sq in. To obtain safe values for the fatigue limits, all of Tapsell's values were therefore multiplied by the ratio 55,000/63,800, obtaining:

Temperature, deg F	Fatigue-limit stress, 1000 lb per sq in.			Proportional limit, short-time test, 1000 lb per sq in.	Tensile strength, short-time test, 1000 lb per sq in.
(1)	(2)	(3)	(4)	(5)	(6)
70	0 ± 24.1	21.2 ± 21.2	42.5 ± 14.5	30.9	55.0
212	0 ± 23.7	20.3 ± 20.3	40.6 ± 15.4	35.1	58.8
392	0 ± 23.7	22.3 ± 22.3	44.4 ± 21.2	26.0	72.6
572	0 ± 30.9	29.0 ± 29.0	57.9 ± 15.4	16.6	66.2
752	0 ± 32.4	25.1 ± 25.1	46.3 ± 11.6	12.6	53.6
932	0 ± 22.6	16.4 ± 16.4	27.0 ± 11.6	9.7	37.4

It may be mentioned that the proportional-limit stress and creep-limit stress were taken the same in compression as in tension.

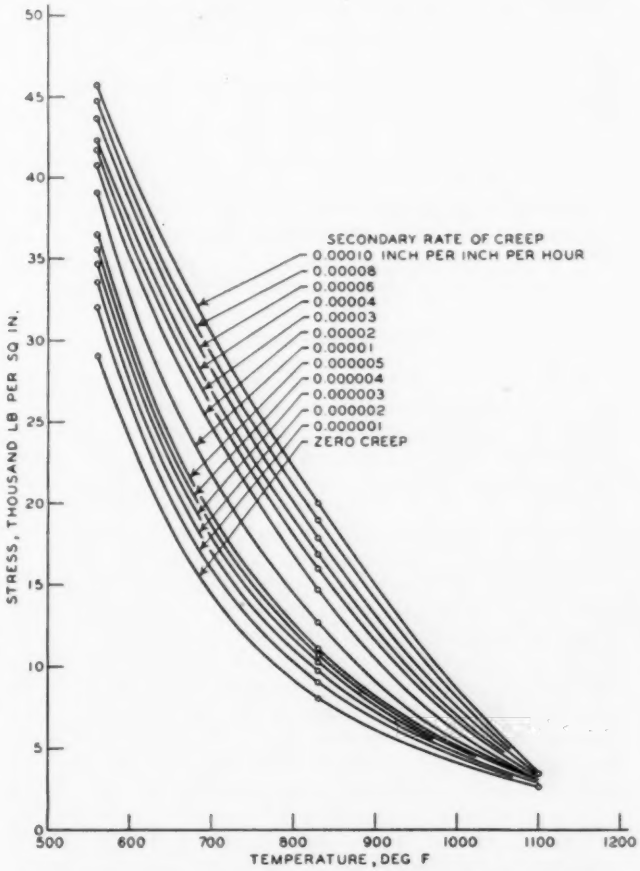

FIG. 39 SECONDARY RATE OF CREEP OF MILD CARBON STEEL AT ELEVATED TEMPERATURES

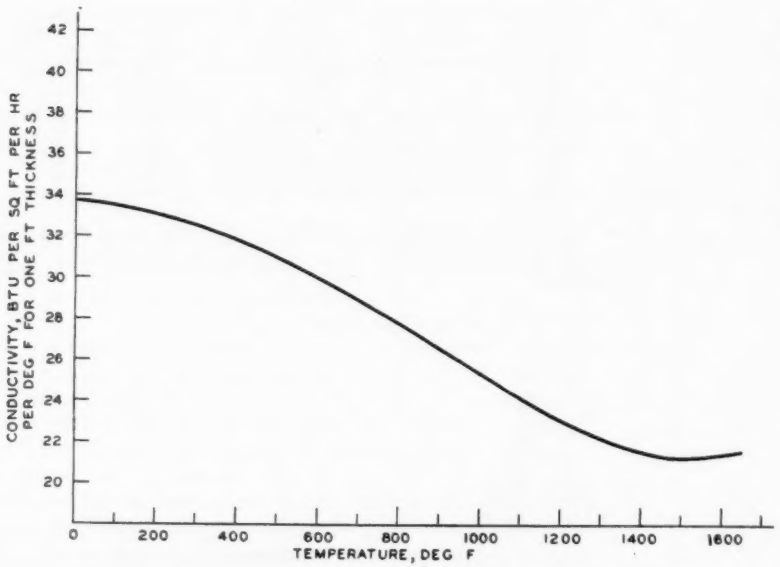

FIG. 41 COEFFICIENT OF THERMAL CONDUCTIVITY OF MILD CARBON STEEL AT ELEVATED TEMPERATURES

criterion, however, is the results secured in long-time service, which should be the governing factor in establishing any set of rules.

The author says that the investigations show that an increase in tube safety is secured by using thicker rather than thinner tubes as called for by the A.S.M.E. Boiler Code.

The new German rules, enacted by the Imperial Minister of Public Works, on July 13, 1931, sanction the use of thinner tubes than those specified in the old German rules or in the A.S.M.E. Code. This was done with the idea of securing improved results, especially at high rates of heat transfer. The A.S.M.E. and new German rules follow:

$$\text{(A)}\quad P = \frac{(t - 0.039)}{D} \times 18{,}000 - 250$$

$$\text{(B)}\quad P = \frac{(t - 0.0394)}{d} \times 18{,}200$$

$$\text{(C)}\quad P = \frac{(t - 0.0394)}{d} \times 22{,}750$$

Discussion

D. S. JACOBUS.[2] Analyses have been made to determine the effect of stresses induced by transmitting heat through the tubes, but so far as is known this is the first attempt to show in a quantitative way the modifying effect of plastic flow. That plastic flow is an important element was brought out in a paper which the writer read at the Annual Meeting of the Society in 1929.[3] It is well known that the effect of creep is to make the stress more uniform than indicated by the elastic theory.

By far the greatest number of tube failures are caused by deposits on the inside of the tubes, and there is no means of making tubes immune to such failures if they are not kept clean. Failures which occur through the accumulation of matter inside of tubes usually result from local overheating, and the consequent bulging of the tubes gives a much different distribution of forces than assumed in the usual analyses. The conduction of heat away from the part which is locally overheated to cooler parts of the tube is facilitated through using thicker rather than thinner tubes. The author has simplified the analysis by assuming that the internal surfaces of the tubes are clean and computed the magnitude of the effect of plastic flow under these conditions in reducing the stresses. Analyses of this sort are of great value in setting forth the elements entering the problem. The final

where

P = maximum allowable working pressure in lb per sq in.
t = thickness of tube wall, in.
D = outside diameter of tube, in.
d = inside diameter of tube, in.

Formula (A) is the A.S.M.E. Boiler Code formula for seamless steel tubes in which the tensile strength may be as low as 45,000 lb per sq in. It is also for lap-welded steel tubes for pressures below 875 lb per sq in.

Formula (B) is the new German formula for tubes of a mild steel having a tensile strength of from 49,800 to 64,000 lb per sq in.

Formula (C) is the new German formula for tubes of steel having a tensile strength of from 64,000 to 78,000 lb per sq in.

A comparison of the tube thickness as required by the A.S.M.E. Code rules and the new German rules is given in Table 5 and of the pressures for given thicknesses in Table 6.

The figures in the tables show that the new German rules sanction the use of much lighter weight tubes than called for by the A.S.M.E. Code.

The new German rules were prepared by a subcommittee of the German Steam Boiler Code Committee of the Vereinigung der Grosskesselbezitzer e.V. (Association of Boiler Proprietors, Inc.). An abstract of an article by E. Lupberger entitled "Discussion of Heated Tubes in High-Pressure Boilers," appeared in the December, 1931, issue of *Mechanical Engineering*.

	C	419	576	779	1035	1283	1621	1744	2060	2391	2784

[a] Formula A is from A.S.M.E. Boiler Code; B and C are from the new German rules, B being for tubes of steel having a tensile strength of 49,800 to 64,000 lb per sq in. and C for steel having a tensile strength of 64,000 to 78,000 lb per sq in.

This article contained diagrams (Fig. 13) which showed the stresses in a tube 83 mm (3.27 in.) outside diameter when subjected to radiant heat. The diagrams gave the stresses for various wall thicknesses and for three rates of heat transfer. The stresses for the different rates of heat transfer were computed on the basis of the elastic theory, and the results secured by using the old German rule and the new German rule for the milder steel (formula (B) of this paper) were shown in the diagrams. On these the writer marked by crosses the thickness required by the A.S.M.E. Boiler Code rules for a tube 3.27 in. outside diameter at the different working pressures which are given in atmospheres on the curves. For example, in the curves marked 60 metric atmospheres (853 lb per sq in.) the thickness of a 3.27 in. diameter tube required by the A.S.M.E. Code would be 0.239 in. (6.08 mm), and a cross is placed on each of the three curves for 60 atmospheres, corresponding to 6.08 mm. The diagram as marked showed that the A.S.M.E. Code thicknesses approach the most advantageous thickness given by the curves more nearly than those obtained by the new German rule for heat transmission of 36,880 and 18,440 Btu per hr per sq ft, whereas at the higher rate of heat transmission of 73,750 Btu per hr per sq ft the new German rule approaches more nearly to the theoretical figure than the A.S.M.E. rule. They also showed that the A.S.M.E. Code rules call for somewhat thinner tubes in most cases than the old German rules.

The heat-transfer rates given in Mr. Lupberger's paper are much lower than those which exist in power-plant practice, where 100,000 Btu per sq ft and considerably over must often be provided for. It should be borne in mind that the most highly heated portion of a tube must be considered. The modifying results of plastic flow would reduce the maximum stresses below those shown by the elastic theory and the stresses for the lower transfer rates by the elastic theory would approach the maximum stresses which would actually exist at some higher rate of heat transfer.

Mr. De Baufre's analysis shows that for a tube 3 in. outside diameter, having a wall 0.425 in. thick and subjected to a working pressure of 1840 lb gage, or 125 atm, the maximum stress for a rate of heat transfer of 90,000 Btu per hr per sq ft is about 17,000 lb per sq in.

It will be seen on comparing this stress with the stresses given in the diagrams (Fig. 13) of Mr. Lupberger's paper that it is considerably less than would be obtained by an analysis where the effect of creep is not included. If Mr. De Baufre will add to his paper curves similar to those given in Fig. 13, it would be a valuable contribution. It would also add greatly to the value of the paper to give the stresses for heat-transfer rates of 125,000 and 150,000 Btu per hr per sq ft.

The Boiler Code Committee has sanctioned the use of higher carbon-steel tubes than specified in the code, with an upper carbon limit of 0.35 per cent and having a minimum tensile strength of 60,000 lb per sq in., in order that these tubes may be used under conditions where they are subjected to radiant heat and the rate of creep is an important element. These higher carbon-steel tubes have been sanctioned for use at pressures not to exceed those allowed by the code for lower carbon-steel tubes of the same thickness. This limitation does not count against the advantages secured in using the tubes under conditions where they are subjected to radiant heat and a high heat transfer.

Summarizing, it seems to the writer that for ordinary operating conditions the tube thicknesses specified in the A.S.M.E. Boiler Code are as nearly correct as can be shown by any theory. Extreme conditions of heat transfer should be met by employing tubes of a higher carbon content or of special alloy steel of the same tube thicknesses as given in the code for tubes having a lower carbon content. For small-diameter tubes of forced circulation boilers it is advantageous under certain conditions to reduce the thickness below that called for by the A.S.M.E. Code.

GEO. A. ORROK.[4] The mathematics of the paper is clear and logical, and the picture of the processes taking place in the stressed metal as presented is clear and convincing. The author gives ample mathematical formulas for the calculation of any design problem of boiler-tube surfaces, presenting also those situations where the lessons of experience are indicated. The writer is not going to discuss the mathematical side of the paper, but will call attention to the question of temperature margin with some suggestions from operating experience.

The cost of maintaining boiler surface in operating condition includes the regular cleaning and renewals of deteriorated surface at stated periods, as well as those much more expensive and annoying forced-maintenance periods caused by the appearance of blistered, burned, or burst tubes. If an increased thickness of boiler-tube metal would reduce the second part of the expense, then the additional cost of metal would be amply repaid. But unfortunately the greater thickness of tube metal is not a guarantee against the effects of scale accumulations, poor circulation, flame impingement, and their consequent troubles.

A boiler tube exposed to the radiant heat of the furnace operates at a temperature margin to softening of perhaps 200 to 300 F, and the thicker the tube the lower must be this temperature margin. The gradual increasing of tube thickness above the code value is equivalent to wrapping the tube with successive layers of more and more plastic metal, which tends to increase the stress and strain on the inner layers until the latter also become plastic and creep sets in. Thus a thick boiler tube wall will have some internal layer truly elastic covered both inside and out by plastic layers. It is evident that the greater the thickness of the tube with the same steam temperature the higher will be the temperature of the outside of the tube and consequently the

[4] Consulting Engineer, Orrok, Myers & Shoudy, New York, N. Y. Mem. A.S.M.E.

less temperature margin for meeting the uncontrollable exigencies of operation. Mellanby and Kerr in England were the first to point out that the temperature margin is the only real factor of safety. We know that in high-pressure boilers a very small amount of scale decreases this temperature margin to a large degree, usually resulting in a bulge or a blowout.

There has been a great deal of discussion about the embrittlement of overstressed metal in riveted joints. We are not sure that the metal of a thick tube overstressed by heat transfer would not develop a widespread embrittlement in certain conditions. Moreover, a comparison of service given by boiler and superheater tubes when exposed to radiation shows that, on the average, the latter have a shorter life. If a worn-out radiant superheater tube is inspected, a substantial loss of weight on the side exposed to the heat can be usually found which is due mainly to outside oxidation. Boiler tubes with a cooler outside surface stand much better. Thus thick tubes will be reduced to thin tubes on many square feet of surface toward the middle and end of their useful life. This difficulty is aggravated when high-carbon and alloyed steels are used with their lower heat conduction characteristics.

On the assumption of one stress cycle per day, the author considers thick tubes as immune to fatigue cracks, but there are many locations in the water walls and in the convection zone where partial stress cycles will be occurring every second or so due to peculiarities of circulation of both water and gas, and the writer is not so sure that fatigue cracks would not develop under such circumstances. Certain difficulties of this type have been manifest even in low-pressure boilers. It is needless to say that the higher the outside tube-metal temperature the more the situation is aggravated.

Our many experiences with boiler tubes which have been deformed by pressure and heat lead also to the conclusion that it is not only the mean temperature of the tube wall which is of importance, and again following Mellanby and Kerr, the main criterion is the temperature of the outside surfaces of the tube. When this temperature exceeds the creep limit, deformation invariably takes place, even though the mean temperature of the wall is higher than the creep-limit temperature figuring on the whole section. Our efforts should be directed toward keeping the temperature of the outside tube surface exposed to radiant heat within proper bounds, in which case the mean temperature of the tube metal will take care of itself and be safe enough for all purposes.

Those of us who have seen tube and header walls of thicknesses exceeding $^3/_8$ or $^1/_2$ in. after exposure to radiant heat can testify to the extensive deterioration which invariably takes place.

All the properties of steel defining its stability under stress in boiler operation are adversely affected by temperature, and the writer's preference is always for the coolest tube under the operating conditions.

The author considers that the safest thickness for boiler-tube walls is that thickness in which the ratio of the internal fluid pressures to the proportional limit stress at the mean wall temperature is the highest, which statement, carried to its logical conclusion, predicts an infinitely thick tube. The writer is inclined to believe that this statement requires further argument. As a corollary he also suggests that the safety of a tube may be increased by using materials with a higher proportional limit stress. This would without doubt be true if the heat conductivity of the material were of the same order. But it appears also to be true that as the carbon content or the alloy percentage of the steel increases, the coefficient of heat conductivity is cut down to about one-third of the figures for ordinary mild steel, thus increasing the outside temperature of the tube by many degrees for the same heat conductance. From data taken from the International Critical Tables, the coefficient of heat transfer for ordinary tube steels is of the order of 45 to 48, decreasing to as low as 16 with the increase of carbon content or of alloying materials. The data, however, are fragmentary, and much more actual experimental work is required with various samples of steel before judgment should be passed.

His conclusions regarding the coefficient of heat transfer from the inner surface of the tube wall to the water-steam mixture are most interesting and show well the dangers of poor circulation and scale accumulation.

The appendixes will be valuable to all engineers who are concerned with boiler design, and it is hoped that with the aid of such tools as these we may get a much better understanding of the physical processes lying behind boiler-tube failures.

N. Arstay.[5] Many authors have treated this subject of boiler-tube stresses, but this is the first paper in which a concrete example has been treated exhaustively and all factors have been taken into account. Moreover, it gives a clear picture of the successive states in the tube metal. The case in its general aspect may be stated briefly thus: A tube subject to inner pressure and high heat input from the outside develops tension stresses at the inner surface which are beyond the creep limit, and hence the tube will deform, releasing the stress. Successive operating runs of the boiler will effect a residual compression of the inside fibers which crept during the operation. Thus on each starting of the boiler before stressing the inner fibers to full tension, the compression would be relieved, and hence the maximum operating tension strain and stress due to pressure and heat transfer will be less than that calculated for a perfectly elastic tube in the initial state. In this sense the tube will become very much like any big gun built of cylinders shrunk one on the other with pressure decreasing outward. It is clear that the full effect of creep in the most stressed fibers will ultimately amount to the reduction of total stress at the inner fibers to the zero creep stress, or a very slow creep, according to the other viewpoint, at the temperature of metal. In other words, the thermal stresses are of secondary or less importance, being mostly relieved by creep.

The question now is which tube will be safer—the thick one preset by the creep or the thin one with low thermal stresses. This question is still unanswered. We know that, in general, tubes of A.S.M.E. Code thickness fail only in locations of scale accumulations or in locations where flame impingement produces heat inputs well above the 90,000 Btu per hr per sq ft used in the paper as maximum. The general tube distortion has been observed only in overheated superheater tubes, which, by the way, usually are relatively thicker.

The useful temperature range for the metal is narrow, let us say from 550 to 1100 F, being defined below by the saturation temperature and above by the serious softening of the metal. The cleanliness of the inner surface will affect the metal temperature greatly, and in the hot spot due to scale there will be creeping and a bulge, irrespective of the initial thickness of the tube. It will take a somewhat longer time for a thick tube to develop the bulge, but the result will be identical with the case of a thin tube. It is obvious that if the scale settles in the tubes, the process of bulging in both the thick and the thin tube will be the same, separated only by a time interval which is insignificant compared with the usual operating runs. Both tubes will suffer equally, and there is no marked advantage in the thick tube. Recently, the German boiler code has been revised and thinner tubes specified.

In the case of flame impingement we must distinguish between the continuous impingement due to an unfortunate furnace and

[5] Principal assistant engineer of Geo. A. Orrok, Orrok, Myers & Shoudy, New York, N. Y. Mem. A.S.M.E.

burner design and the occasional impingement, when the flame licks a tube now and then, here and there. For the continuous impingement with heat inputs upward of 120,000 Btu per hr per sq ft, allowing for creep, the tube will be stable in a continuous operation when the pressure stress in the inner fibers is under the zero creep stress at the temperature, irrespective of the thermal stress. When shutting down the boiler, the thermal stresses in the tubes will be relieved. If the metal temperature is below the stress-relieving point, the permanent set will maintain the inner compression and outer tension, but if the tube is kept several hours at a temperature in which these forces are relieved, the tube will return to the initial stress state, but not to the initial shape, and thus the creep deformations will be cumulative with every lighting up. Banking periods with tubes not quite clean will be very favorable for this release of residuary stresses. It is very difficult to say without experimental data just in which direction the accumulation of deformation will go. For the intermittent impingement the question is more indefinite; on one hand, we have a more frequent change of stress and release of residuary stress favoring residual deformation, but on the other hand, the time for creeping is reduced.

Some years ago the writer made a study of stresses in the connections of longitudinal fins with tubes in the usual water-wall construction. The stresses are enormous if the metal of the fins does not yield, and the writer has found that the fins and the welds are entirely plastic, closely following, without serious stresses, the thermal changes. That was the only possible explanation of the usually good service performance. It should be noted here, however, that the creep in this case is almost wholly the compression yield in the fin, when the boiler is lighted. The high temperature of the fin's metal allows a fast releasing of the residual tension stress when the boiler is being shut down, so that the metal of the tube is not affected adversely. We have many instances where fin tubes have given several years of splendid service, and this shows that a plastic state in certain portions of the tube metal has no inherent danger.

It becomes more and more obvious that the creep depends upon many factors. Unfortunately, very little is being done to ascertain the effect of compound stresses. The shear creep tests have just begun. The change in density of the metal which crept, if such changes occur, has not been compared with the change of density in metal worked cold to the same residual deformation. It would be very interesting to rupture in tension a few specimens of tube steel which were subjected to various extensions by creep and to see how a degree of extension by creep affects the tensile properties. The writer does not know of any series of experiments in which boiler tubes were tested to destruction, and the need for such experiments is apparent at present when the high steam pressures are becoming common.

This question of boiler-tube thickness is sufficiently important to warrant a series of experiments, which might be as follows:

(1) Selection of a hard-driven high-pressure boiler which is losing tubes and insertion of a few tubes of varying thickness in the water walls of first rows. The comparative service given by the tubes of various thickness will be the indication by which to judge the economy of greater metal thickness.

(2) A series of experiments with a small forged-steel drum and several U-tubes of various wall thicknesses connected to the drum and subjected on some definite portion to a very high rate of heat transfer by radiation—for instance, by placing them in a carborundum cavity heated intensely and to the direct flame impingement of gas burners, the observer to be protected of course. If this program should be carried out, then the processes of tube failures due to thermal and pressure stresses might be ascertained. So many factors usually enter into the common tube failures that the effect of tube thickness is never observed nor ascertained.

C. F. Hirshfeld.[6] One of our findings in Detroit may offer a means of advancing knowledge in the field under discussion. We deal here, among other things, with the question of plastic flow of steel. This is a subject that is rather difficult to study in the laboratory because of the difficulties imposed by the necessity of working with the metal at relatively high temperatures.

In studying the behavior of lead cable sheaths at duct temperatures we found ourselves in the field of plastic flow. It occurred to some of us that there might be a resemblance between the behavior of lead and of steel, except that corresponding phenomena occur at different temperatures. To test the idea we had an investigation conducted at the University of Michigan. This showed that lead at low temperatures becomes quite an elastic material in the sense that it gives the same type of stress-strain curve that steel does at ordinary temperatures. This finding suggests that we might use lead at ordinary temperatures to indicate qualitatively what may be expected of steel at high temperatures. The writer suspects that experiment along such lines would prove fruitful in advancing our knowledge of the type of phenomena concerned in the use of steel at elevated temperatures.

Clarence H. Kent.[7] The problem of the thermal stresses in a tube subjected to heat flow on one side only is entirely new. We have known that creep must relieve thermal stresses in such applications as the tubes of oil stills, and the author's application of the known data on creep to this problem is interesting.

In the past boiler tubes have been treated as thin cylinders, but the increase in thickness necessitated by high pressures has rendered this method less and less exact. When tubes are treated as thin cylinders, the temperature distribution becomes a linear function of the radius, as in Equation [2] under the heading, Axial Stresses in Cylindrical Tube Wall Before Bending, instead of the actual logarithmic function as given in the first part of Appendix No. 1. In calculating stresses set up by temperature difference or by external forces the radial stress is neglected in the case of thin cylinders. In the examples which the author has considered, the radial stresses have been found to be too low for practical consideration.

The axial and circumferential thermal stresses of Fig. 3 would have shown a maximum variation of approximately 11 per cent from the curves shown had the cylinders been treated as thin. Thus no very large error is introduced even with the cylinders considered in using the very simple relations for these stresses developed for thin cylinders: $\max t_t = s_t = \pm \frac{E\alpha m}{2(m-1)}(T_2 - T_1)$ in the author's notation. If the use of the more complex equations given on the third page is desirable, one is referred to *Engineering*, vol. 124, 1927, p. 443, in which Mr. L. H. Barker presented some very useful alignment charts for the solution of these equations.

It will be noticed that the sum of the radial and tangential thermal stresses equals the axial stress, or $p_t + t_t = s_t$, as shown by the author's equations or curves. This is true for all kinds of thermal stresses in cylinders when the distribution is symmetrical about the axis of the cylinder, and forms a quick check on the accuracy of numerical results.

Attention should probably be called to the fact that the equations for thermal stresses presented in the paper may be applied only to that portion of the tube not near the ends. Obviously the thermal axial stress must reduce to zero at the free ends, and the circumferential stress may increase as much as 35 per cent

[6] Chief, Research Department, Detroit Edison Company, Detroit, Mich. Mem. A.S.M.E.

[7] Professor of Mechanical Engineering, Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

above that calculated for the middle section. The exact distribution will depend, of course, on the end conditions. The length of this end section in which the equations developed do not apply is in turn dependent upon the cylinder dimensions and probably would not exceed 12 inches in this case. The writer gave solutions of this problem for various end conditions for thin cylinders which could be applied with reasonable accuracy in this case.[8]

At the top of the sixth page the author is apparently justifying the use of the maximum-stress theory in determining the point at which the material reaches its elastic limit. On the page preceding he has determined the circumferential strain by dividing the circumferential stress by the modulus of elasticity, instead of by the more usual formula: $e = \frac{1}{E}\left(t - \frac{s}{m}\right)$, if the radial stress is neglected and e represents the unit circumferential strain. If one applies the strain-energy theory for ductile materials, one finds that it would require a single stress of 29,100 lb per sq in. to equal the maximum applied circumferential stress of 26,344 lb per sq in. and axial stress of 22,561 lb. If the proportional limit in Fig. 4 is 14,000 for a single stress, the same strain energy will be produced by two equal principal stresses of 11,830 lb per sq in.

The choice of one or other of these theories would not affect the method used by the author to determine the probable circumferential stress, but the use of the latter theory, for instance, would increase the spread between probable and calculated values in Fig. 9. Lack of data prevents general agreement on any particular theory of combined stresses, but it is usually considered that the proportional limit is less for combined stresses of this character than for single stresses.

Referring to the first part of Appendix No. 1, the writer questions whether it is necessary to repeat here the derivation of standard formulas given in the textbooks. The principle of superposition shows at once that the total stress in the tube wall is the sum of those produced by internal pressure and those produced by temperature difference.

In the second part of Appendix No. 1 the author has developed expressions for stresses in a tube subjected to heat flow on one side only. The writer believes it is possible to obtain more exact values for the stresses involved, still treating the tube as a thin cylinder, as the author has done. If we consider the tube split into two semi-cylinders, that part subjected to heat flow will experience a change in curvature in two directions—one parallel to the axis and the other at right angles to it. The change in radius of curvature is given by $r = \frac{t}{\alpha(T_2 - T_1)}$; this change of curvature may be removed by the application of moments in the two planes considered whose value is $M = -\frac{EIm}{m-1}\frac{\alpha(T_2 - T_1)}{t}$. The stresses produced by these moments in each of the two directions are $\max s_l = t_l = \pm \frac{E\alpha m}{2(m-1)}(T_2 - T_1)$, which is the same as the stresses in a thin plate subjected to the above moments in two planes. This compares with the author's formulas [9] and [10] under the heading referred to, in which he has omitted the factor $m/(m-1)$, as he has done also in Equations [7] and [8].

By the application of these moments, that half of the tube subjected to heat flow is now straightened in the axial direction and restored to its original curvature in the circumferential direction. It must then be joined to the half in which there is no heat flow and which is subjected to no moments. This will produce bending in a plane through the axis until the moments in the two halves are equal, as the author has considered. But there must also be both moments and shear applied to the edges of the two halves to bring the edges together and then to equalize the slope of their walls. These the author has not considered as affecting the circumferential stresses and through these the axial stresses. Upon these thermal stresses we must superpose those due to internal pressure.

A. E. R. DE JONGE.[9] Dr. Lohrisch has shown[10] that the distribution of heat absorption in a boiler tube is qualitatively about as indicated in Fig. 42. If a front-row tube is considered, the heat absorbed by radiation has to be superposed so

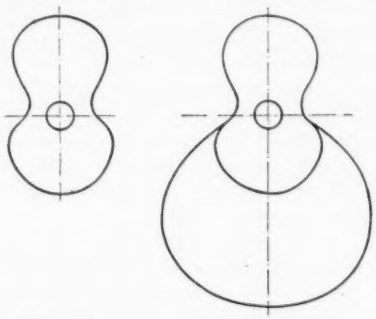

FIG. 42 FIG. 43

that the heat absorption of the boiler tube would be changed somewhat as indicated in Fig. 43. The writer would like to ask the author how this distribution of heat absorption will modify the stresses from his assumptions—i.e., how the longitudinal and the circumferential stresses will be distributed. It seems that the longitudinal stresses are somewhat eased, while the circumferential stresses become worse and probably set up a bending over the transverse cross-section of the tube. It would be interesting to hear from the author what their effect will be on the tube—i.e., both in longitudinal and transverse direction.

AUTHOR'S CLOSURE

Referring to the suggestion of Dr. Jacobus that curves be added to the paper similar to those given by Mr. Lupberger and that stresses be given for heat-transfer rates of 125,000 and 150,000 Btu per hr per sq ft, time has not provided the opportunity to do so. It might be added that while the curves of Mr. Lupberger do not show the maximum stresses to which the tube wall is subjected by reason of creep with high rates of heat absorption, they do show the ranges in stress; for to the extent that tension is relieved by creep, a compressive residual stress is set up in the material. If temperature stresses contribute to the failure of a boiler tube, the failure must be due to fatigue at the inside surface, which will be a function of the stress range.

Referring to Mr. Orrok's comparison of boiler tubes and superheater tubes, it may be mentioned that the paper is limited to boiler tubes. The conditions in superheater tubes are different from boiler tubes by reason of the higher temperature of the fluid within the tube and the lower rate of heat transmission from the inner tube wall to this fluid.

Mr. Orrok also refers to the lower heat conductivity of high-carbon and alloy steels as compared with the mild carbon steel usually used in boiler tubes. For mild steel boiler tubes, the heat conductivity of the metal is around 30 Btu per hr per sq ft per deg fahr for 1 ft thickness under ordinary temperature conditions, as shown by Fig. 41, instead of 45 to 48 as mentioned by Mr. Orrok. For medium carbon steel, 0.35 per cent

[8] "Thermal Stresses in Thin-Walled Cylinders," Trans. A.S.M.E., 1931, APM-53-13, p. 167.

[10] *V.D.I. Forschungsarbeiten*, heft 322, pp. 46–68 (1930).

carbon, the heat conductivity will be reduced only to about 28 instead of to 16 as mentioned by Mr. Orrok. Even 3.5 per cent nickel will only reduce the heat conductivity of steel to 23 to 25, depending upon the carbon percentage. The slightly higher metal temperatures due to these decreases in heat conductivity would not counterbalance the advantages of the higher creep limit with medium carbon steel and with 3.5 per cent nickel steel as compared with mild carbon steel in boiler tubes.

In answer to Mr. de Jonge, the conditions shown by him are less severe than assumed in the paper for a tube receiving heat on one side only. The absorption of any heat by the rear of the tube would reduce the axial stresses as calculated in the paper. The discussion of Professor Kent, however, shows a better method of attack than used in the paper for calculating the stresses in a tube wall with non-uniform heat absorption, and it would be interesting to apply this method to the heat-absorption distribution shown by Mr. de Jonge.

The use of thinner tubes than specified by the A.S.M.E. Boiler Code would have a number of advantages, as listed in the article referred to by Dr. Jacobus; and the practical results of the German experiment in using such tubes will undoubtedly be watched with interest by all manufacturers and users of high-pressure steam boilers. One practical disadvantage to the use of thin tubes, however, is the absence of any margin of safety where corrosion is likely to occur, either externally as mentioned by Mr. Orrok or internally. Unfortunately, a thick tube wall would not prevent failure of boiler tubes by poor circulation of the water-steam mixture within the tubes, by accumulation of scale on the inner surface of the tube wall, by flame impingement on the outside of the tube wall, by corrosion of either the inner or outer surfaces, or by defective material.

The author agrees with Dr. Jacobus that the tube thicknesses specified in the A.S.M.E. Boiler Code are as nearly correct as can be shown by any theory. It is questioned, however, whether thinner tubes should be used for small diameter tubes of forced circulation boilers.

Pulsation of Air Flow From Fans and Its Effect on Test Procedure

By HAROLD F. HAGEN,[1] BOSTON, MASS.

Error that results from velocity-pressure determinations of volume when a pulsating velocity exists is discussed theoretically. The paper also shows experimentally that such pulsation is of frequent occurrence, and gives quantitatively the amount of the error. It further suggests necessary changes in fan-testing procedure.

THE method of testing fans that has been in use for the past decade is based on a volume determination obtained from a weighted average of velocity pressures. The procedure has been coded, and the resultant standardized testing has proved of great help to both manufacturer and user. However, certain inconsistencies have appeared in the development work of the industry from time to time until the weight of evidence that something is wrong with the accepted method of testing can no longer be ignored. The most important of these inconsistencies may be described briefly.

A few years ago an authoritative laboratory reported that the total efficiency of a certain fan could be increased by the use of an expanding chimney on the fan outlet, the so-called evasée stack. As no ultimate work can be done in a stationary passage, the reported increase of efficiency violated the general law of the conservation of energy, and Bernoulli's law in particular. The author secured confirmation of the reported result when using standard test procedure, but a simultaneous measurement of the volume with a flow nozzle showed 18 per cent less volume than was indicated by the pitot-tube traverse in the large duct. With this reduction in volume, the effect of the chimney was found to be a slight decrease in total efficiency, which of course was in obedience to natural laws and the effect of friction. At the time, poor distribution of air velocities in the large duct was accepted as the explanation of the error. The explanation was disquieting, however, because there was no provision in standard test methods to guard against such a false result.

Recently, propeller fans with only two blades were introduced, which on test showed efficiencies unreasonably high. Tests on multi-blade propellers of the same design showed much lower efficiencies. This decrease in efficiency with increasing number of blades seemed to require explanation.

A third element came from the apparently unexplainable agreements and differences encountered in attempting to check pitot-tube traverse determinations with flow-nozzle volume. In many cases agreement between the two would occur with great exactness; in other cases, even when the extenuation of poor distribution did not apply, differences of a magnitude beyond any reasonable test inaccuracy would appear.

If there were a pulsation in the air, all these inconsistencies would become understandable. In the large duct from the expanding chimney a pulsation could produce a large error. Fewer blades, as in the case of the propeller fans, might tend to create a more violent pulsation and falsely indicate a higher efficiency. And the differences and agreements between nozzle and pitot-tube volumes would be explained by the presence or absence of pulsation. The hypothesis appeared worthy of experimental investigation, particularly when it was realized that with the instruments used for air measurement a high-frequency pulsation would escape detection.

The existence of more or less cyclic variations of air velocity had been noted by various investigators. It had been observed in wind-tunnel experimentation. Also, in connection with some measurements on the intake flow to internal-combustion engines, the possibility of pulsating flow had been realized and the resultant error in pitot-tube indications had been calculated. Experimenters, working with a special hot-wire anemometer, had taken oscillographs of pulsation in both air and water currents.

A velocity wave is accepted, and accepted without question, when the actuator is a displacement engine. The code for testing reciprocating compressors specifies equipment designed to eliminate velocity pulsation. But it has been assumed that a fan rotor gives a steady flow, and all fan testing has been based unquestioningly on this assumption.

The error introduced by unsuspected pulsation is somewhat analogous to the difference between the average and the effective values of a rectified alternating-current wave. In the electrical measurement the effective value wanted is the square root of the average of the instantaneous squares. The usual direct-current ammeter gives, instead of this desired value, the average of the first power of the current. With air measurements we want the average of the first power of the air velocity and we get with our instruments the average of the instantaneous squares.

Wave Errors

The possible error may readily be seen from a consideration of the following simple wave forms. Consider an ideal square wave rising instantaneously to a velocity of 133.3 fps, continuing at this velocity for a definite time interval, then dropping instantaneously to zero, and remaining so for the same time interval. Fig. 1 shows this wave graphically. The average velocity is 66.67 fps, and the volume flowing is correctly given by multiplying this velocity by the cross-sectional area of the duct.

The customary procedure with pitot tube and manometers would give a quite different result. With an air density of 0.075 lb per cu ft, the 133.3 fps would be equivalent to 4 in. of water. The average velocity pressure of the pressure wave is 2 in., and this would be registered by the U-tubes. The velocity calculated from this indicated 2 in. is 94.2 fps. We know from our assumption that the average velocity was only 66.67 fps, so that a volume 41 per cent high would be reported. This square

[1] Vice-President in Charge of Research, B. F. Sturtevant Co. Mr. Hagen was born in Brooklyn, N. Y., on November 14, 1884. He received the degree of M.E. from the Stevens Institute of Technology in 1907. He has been engaged in research work in the fan industry since 1911. Many of the large ventilating and mechanical-draft installations throughout the country, of which the Holland Tunnel is an example, are equipped with fans of his designing.

Contributed by the Power Test Codes Committee and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

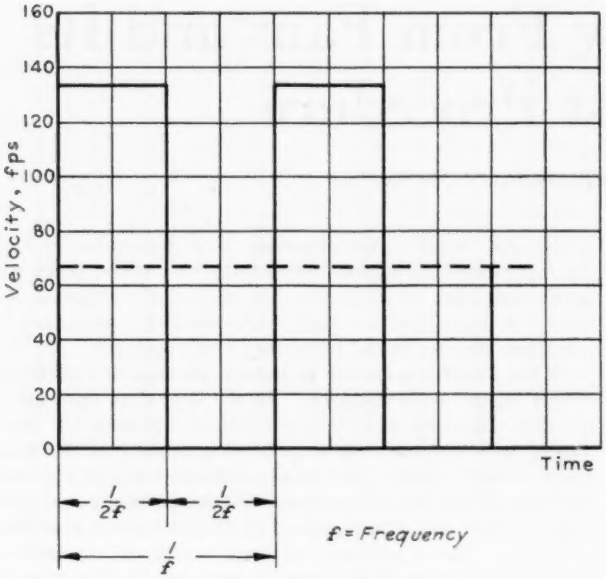

FIG. 1 SQUARE WAVE

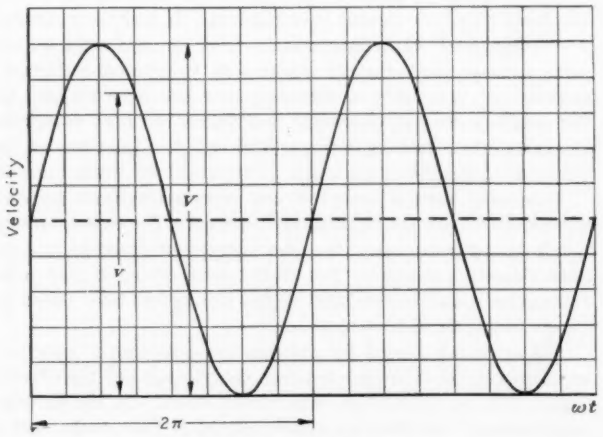

FIG. 2 SINE WAVE TO ZERO

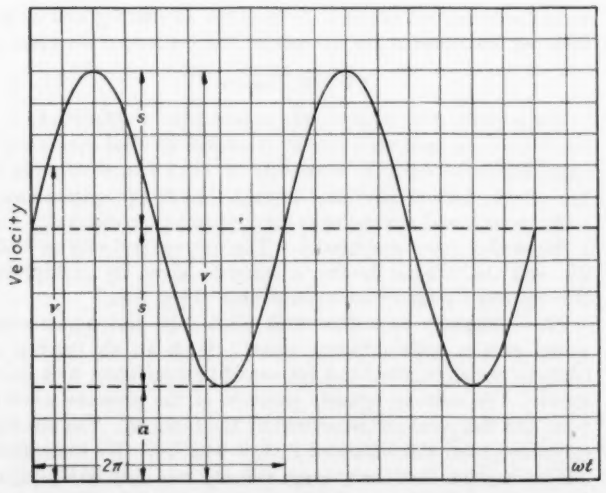

FIG. 3 SINE WAVE TO MINIMUM a AND WITH AMPLITUDE $2S$

wave is of course an impossible condition, but it brings out most clearly the theoretical error under discussion.

A sine wave would more closely approximate true conditions of flow. The sine wave in Fig. 2 represents a pulsation in velocity from zero to a maximum of V and back to zero. The instantaneous velocity v of this wave is

$$v = \frac{V}{2}(1 + \sin \omega t)$$

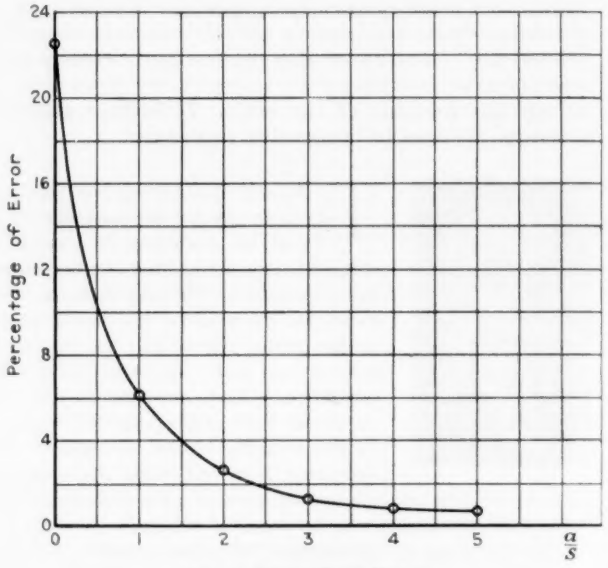

FIG. 4 PITOT-TUBE ERROR
(With sine wave amplitude $2S$ and average $a + S$.)

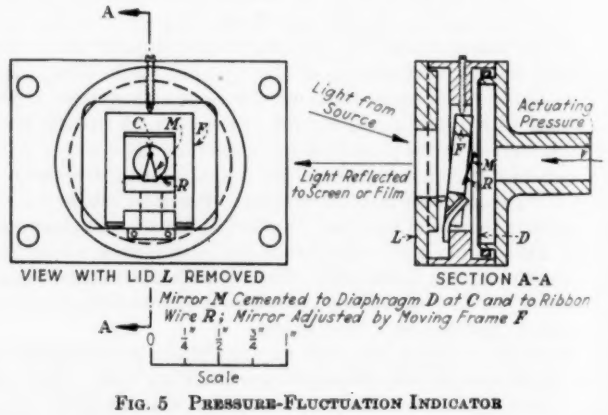

FIG. 5 PRESSURE-FLUCTUATION INDICATOR

and H, the average of $v^2/2g$, is

$$H = \frac{1}{2\pi}\int_0^{2\pi} \frac{v^2}{2g}\, d\omega t = \frac{1}{8\pi}\int_0^{2\pi} \frac{V^2}{2g}(1 + \sin \omega t)^2\, d\omega t = \frac{3}{8}\left(\frac{V^2}{2g}\right)$$

This value would determine the reading on the gages, and the resultant calculated average velocity would be $V\sqrt{(3/8)}$ instead of the correct $V/2$.

The reported volume would be in error in the percentage of

$$\frac{V\sqrt{(3/8)}}{V/2} = 1.225, \text{ or } 22^1/_2 \text{ per cent}$$

A more general case for analysis is shown in Fig. 3, where the sine wave does not drop to zero but to a minimum value a. In this case the maximum velocity $V = 2S + a$, where S is the half-

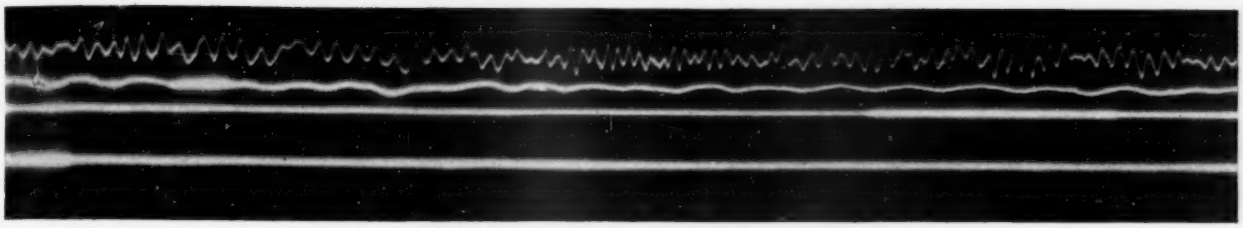

FIG. 6 SPECIAL TEST OF CENTRIFUGAL FAN

(Diagram taken at pitot-tube station. Bottom line, atmospheric; second, calibration line, 0.454 in.; third, average static; top line, impact. Corresponding U-tube readings: Impact, 0.79 in.; static, 0.6 in.; average velocity pressure, 0.2005 in. Film speed, 3.9 in. per sec.)

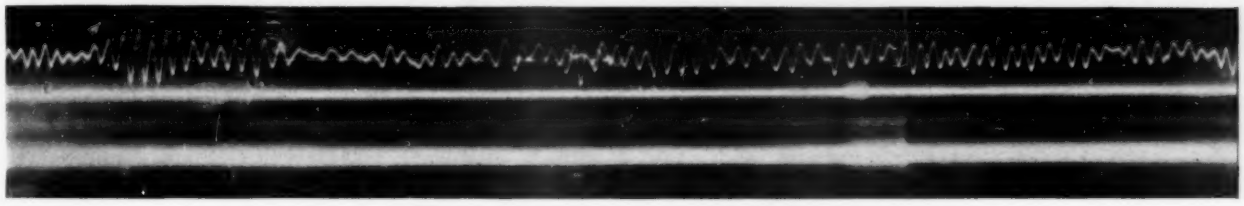

FIG. 7 SPECIAL TEST OF CENTRIFUGAL FAN

(Diagram taken at mouth of nozzle. Bottom line, atmospheric; second, heavy calibration line, 0.54 in.; top line, impact, which in this case is all velocity pressure. Film speed, 3.6 in. per sec.)

amplitude of the wave. The instantaneous value $v = a + S(1 + \sin \omega t)$; and, with H as before,

$$H = \frac{1}{2\pi} \int_0^{2\pi} \frac{[a + S(1 + \sin \omega t)]^2}{2g} \, d\omega t = \frac{1}{2g} \left[(a + S)^2 + \frac{S^2}{2} \right]$$

The true average velocity is v avg $= a + S$, so that the error becomes

$$\frac{\sqrt{\left((a + S)^2 + \frac{S^2}{2}\right)} - (a + S)}{a + S}$$

$$\sqrt{\left(1 + \frac{S^2}{2(a + S)^2}\right)} - 1$$

When $a = 0$, we have the special case of Fig. 2, and the error is $\sqrt{(3/2)} - 1 = 0.225$, or $22\frac{1}{2}$ per cent, as before.

The curve of Fig. 4 shows the percentage of error with varying values of a from 0 to $5S$, or five times the wave half-amplitude. If the error is to be 1 per cent,

$$\sqrt{\left(1 + \frac{S^2}{2(a + S)^2}\right)} = 1.01$$

$$\left(\frac{S}{a + S}\right)^2 = 0.04$$

$$S = 0.2a + 0.2S$$

$$a = 4S$$

Apparently the way to correctness lies in a high a/S. This condition is most readily secured by the use of a flow nozzle at the mouth of which all the head is changed into velocity. In the tests that have been made, the amplitude of the wave appears to be substantially the same at the mouth of the nozzle as it is in the duct, but in the duct the average velocity is small, giving a very small value to a and producing, as a consequence, a small value of a/S and large percentage of error. At the mouth of the nozzle the average velocity is high; a likewise takes on a high value, and the controlling ratio a/S being large, produces a small and perhaps negligible error. Here, then, is the explanation for the differences between the nozzle volume and the pitot-tube volume that, as previously mentioned, have been found in many tests. Further, the peculiar results observed in connection with the expanding chimney fall into line, as in this case, due to the large area of the test duct, the value of a/S became very small, greatly exaggerating the error.

TEST OF PULSATING FAN

To provide a concrete picture of flow vibrations the instrument shown in Fig. 5 was constructed. The figure is almost self-explanatory. A shallow, cylindrical chamber, subjected to the pressure in the duct, is covered with a thin, taut rubber diaphragm D. An adjustable frame F carries a thin metal strip R. (A piece of galvanometer suspension gold ribbon was used.) A small, triangular piece of mirror glass M is cemented near its base to the strip R and at its vertex to the diaphragm D at C. This gives a moving system of small inertia that has a natural frequency very much higher than the frequency of the pulsations of the air in the duct. Figs. 6 and 7 show vibragraphs taken with this instrument.

It will be of value at this point to follow through the actual test results of the fan under test when the pictures of Fig. 6 and 7 were secured. The diagrams of Fig. 6 were taken at the standard pitot station. The lowest straight line was obtained by rotating the film with the diaphragm chamber at atmospheric pressure. The next straight line is a calibration line. The slightly wavy line was secured by connecting the chamber to the static side of the pitot tube. There is often a vibration of considerable amplitude in the static pressure, but the pinholes of the static tube act as an effective throttle. This static line is therefore to be considered only as an average, not as a record of the wave. The usual pitot tube and rubber tubing have passages small enough on both static and impact sides to throttle vibrations, and further have an air column of such length that its natural period of vibration is too slow to follow the high-frequency vibration in the duct. To secure the top line, which shows the wave of the impact pressure, a special short, large-bore impact tube with an air column period less than half the period of the recorded wave was used.

Fig. 7 is similar to Fig. 6, but shows results secured at the nozzle mouth. The atmospheric and calibration lines are located as before. The static line is omitted, as in this case it is identical

with the atmospheric line. The wave is the impact pressure, which becomes at the mouth of the nozzle a pressure due to velocity only. The similarity between the two impact waves of Figs. 6 and 7, both as to form and amplitude, is notable.

Fig. 8 shows the results of test on this same fan, giving both the nozzle results and those determined in accordance with the standard methods of the duct-traverse test. These two sets of curves were obtained by simultaneous measurement, and the difference in volume, approximately 7 per cent, is represented by points on the two curves at the same static pressures.

The test set-up used is shown in Fig. 9. To the fan outlet was connected a transformation leading to the standard cylindrical test duct, with all areas identical. At the far end of this duct an expanding cone with an internal throttle led to a larger duct and a final flow nozzle. The introduction of the large duct permitted

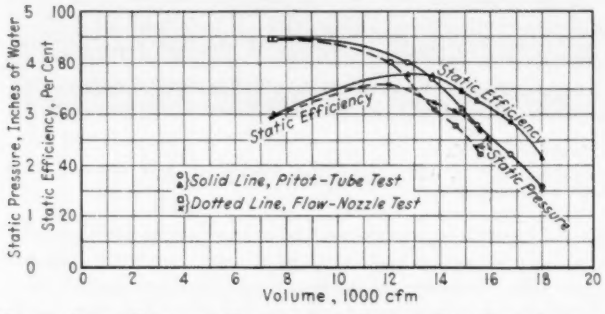

FIG. 8 PITOT-TUBE AND FLOW-NOZZLE TEST OF FAN WITH PULSATING DISCHARGE

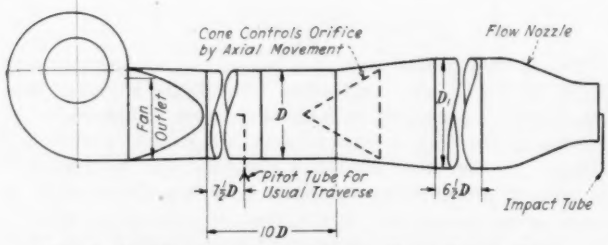

FIG. 9 SET-UP FOR PITOT-TUBE AND FLOW-NOZZLE TEST

the use of a larger nozzle without violating the rule of nozzle proportion—a diameter of mouth not more than half the diameter of the preceding duct—and made possible accurate nozzle determinations of volume throughout the useful range of fan performance. In Fig. 8 this range is from 12,000 to 16,000 cfm. A nozzle connected directly to the end of the smaller test duct would have a maximum area one-fourth of the fan outlet area, and would therefore limit results to the low-volume portion of the fan characteristic, approximately 10,000 cfm, on the curves of Fig. 8. There seems to be no way at present to avoid the increased cost of the test set-up due to the required additional duct.

A nozzle with a mouth diameter approximately seven-tenths of the diameter of the small test duct seems to be most satisfactory where a test is to be made with a single nozzle. The velocity from this nozzle is substantially twice the velocity in the small duct, and the delivery area is sufficiently large to carry the test beyond the useful range of the fan. Where still larger volumes are required, the nozzle mouth may be carried up to the full size of the small duct diameter. In such cases, however, extreme caution should be used and the points secured checked by extrapolation from the points determined from the smaller nozzle.

It is highly desirable, in dealing with a fan that produces a pulsating flow, to use at least one additional nozzle. By means of the conical throttle the same volume point may be secured from both nozzles and the test points compared. An additional nozzle approximately six-tenths of the small-duct diameter is extremely useful in making certain of correct results.

ADDITIONAL TEST DATA

Many tests of fans of different types have been made. Some fans show close agreement between pitot-tube traverse and nozzle; others show discrepancies as high as 18 per cent. Table 1 gives some of these results.

TABLE 1

Fan No.	Type[a]	Blades	Static pressure	Volume—Pitot	Volume—Nozzle	Percentage of error
1	B-S	8	1.5	9,200	9,210	None
2	B-S	8	0.79	11,430	9,825	16.5
3	B-D	8	1.8	14,290	14,370	None
4	B-S	12	1.9	12,680	12,000	5.7
5	B-S	16	0.88	11,520	10,460	10.1
6	B-D	16	2.42	11,720	11,120	5.4
7	B-D	16	2.06	15,250	15,400	None
8	R-S	12	7.25	4,750	4,780	None
9	R-S	12	8.85	5,250	5,030	4.4
10	R-S	12	6.24	4,825	4,460	8.2
11	R-D	12	0.56	25,250	25,900	None
12	R-D	24	1.82	15,100	14,960	None
13	F-S	48	2.1	13,300	11,250	18.3
14	F-S	60	6.0	11,000	10,600	3.8

[a] B denotes backwardly curved blade; R, radial tip blade; F, forwardly curved blade; S, single inlet, D, double inlet.

No specific conclusions can be drawn from these results as to the cause of pulsation. Actual pulsation seems to exist in all fans, but in some the amplitude of the wave is sufficiently small so that errors in measurement do not occur. In other cases, the amplitude is sufficiently large to make wide differences. An error of 10 per cent is not unusual, and in fan No. 13, in Table 1, the error ran as high as 18 per cent. This was the fan, referred to before, that was provided with an extreme expanding chimney. The table appears convincing, however, in the matter of test procedure. It is not safe on any fan to assume the absence of serious pulsation, and when violent pulsations are present, theoretically even a nozzle measurement may be appreciably in error.

Test procedure therefore ought to result in a determination of the presence or absence of pulsation error. With the instruments at present available to the industry, this information can best be secured by making two volume determinations—one by the usual pitot-tube traverse method and one by a nozzle determination at higher velocity. Many engineers dislike the pitot-tube traverse, but it seems to the author from the work in connection with this investigation that the pitot-tube traverse is an extremely accurate method of determining the average velocity pressure in a duct. If, as the result of pulsation, this velocity pressure is incorrectly interpreted as corresponding to the average velocity, the error is with the interpretation and not with the instrument.

It would seem, therefore, that an agreement between the volume determined by the pitot-tube traverse and the volume measured at the mouth of the flow nozzle should be the criterion of correctness of result. A disagreement between these two volumes could safely be accepted as an indication of a pulsation that must be considered.

In extreme cases of difference between pitot-tube traverse and nozzle volumes and where a high degree of accuracy is required (as, for example, when noting the effect of small changes in fan proportions), an additional run of pipe and an additional small nozzle may be used, employing an auxiliary fan, if necessary, to get the required volume through the system. Agreement between the two nozzle volumes determined at different velocities could serve as the required indication of a correct measurement.

It has been noticeable in all the work that the pulsation error is greatest with the larger outputs and that close agreements

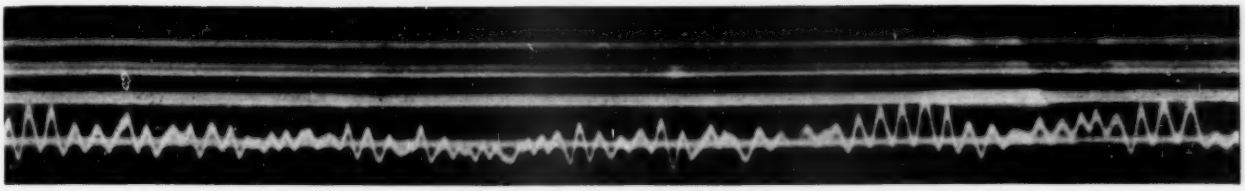

FIG. 10 STANDARD SUCTION-PIPE AND DRUM TEST OF PROPELLER FAN
(Impact tube at pitot-tube station in suction duct. Calibration lines: Top, atmospheric; second 0.2 in.; third 0.298 in.; fourth, 0.714 in. Film speed, 5.24 in. per sec.)

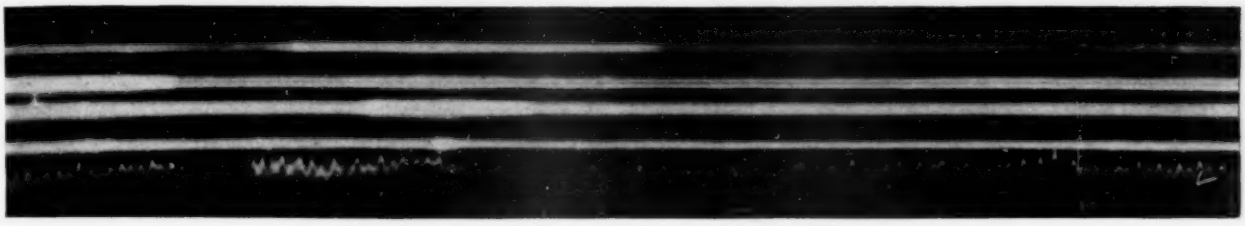

FIG. 11 STANDARD SUCTION-PIPE AND DRUM TEST OF PROPELLER FAN
(Impact tube in drum. Calibration lines: Top, atmospheric; second, 0.266 in.; third, 0.444 in.; fourth, 0.698 in. Film speed, 5.24 in. per sec.)

between pitot tube and nozzle are readily secured at the smaller volumes. This tendency is clearly shown in the curves of Fig. 8 and is typical of practically all the fans tested.

PROPELLER FANS

With propeller fans tested on the outlet side, there seems to be little hope for any consistency. Tests indicate errors of the same general order of magnitude as given in the table for centrifugal fans, but results are widely varying and cannot readily be checked. Contrary to expectation, no difference could be observed in the results of pulsation between two-bladed fans and six-bladed fans. Careful investigation and test reduced the reported efficiencies of these propeller fans to a reasonable point and indicated that the apparently extreme efficiencies were due to a combination of pulsation error and the almost classical mistake of crediting the velocity pressure in the fan intake to static.

The standard procedure for testing propellers provides for readings on the inlet side and the use of a centrifugal fan to overcome the resistances of the duct and drum. Obviously, the results may contain pulsation error, due not only to the action of the propeller fan, but also to the working of the auxiliary, so that propeller fans under customary test methods will give results that vary with the particular centrifugal fan that is connected to the test duct. Even on the inlet side, before the air has passed through the propeller fan, the pulsation appears. Figs. 10 and 11 show vibragraphs taken on the suction side of a two-bladed propeller fan. In this case there was no centrifugal fan used. Fig. 10 shows impact in the inlet duct; Fig. 11 shows impact in the large drum between the inlet duct and the propeller fan. The change of frequency shown in Figs. 10 and 11 is noteworthy. A careful measurement of volume by steam-heater condensation and air-temperature rise indicated an error of 10 per cent in the volume by pitot-tube traverse in the inlet duct corresponding to these diagrams.

It is proposed, therefore, that for the determination of the volumes handled by propeller fans the same general procedure be followed as has been advocated for centrifugal fans—namely, a pitot-tube traverse in the inlet duct and a nozzle determination from a nozzle half the diameter of the duct and discharging directly into the drum from which the propeller fan exhausts. The same requirement for an agreement between the two volumes thus determined would apply.

CONCLUSIONS

From these analyses and tests the following conclusions seem allowable:

1 A variation of velocity can exist in the flow of air past a fixed point.

2 This changing velocity results in an average velocity pressure higher than that corresponding to the average velocity.

3 There can be no certainty of accurate volume determination if the fluctuations are extreme, and consequently accurate testing requires controlling evidence of the magnitude of fluctuation. This evidence may be secured by comparing two volume determinations made at different velocities. A close agreement implies small pulsation and correct results.

4 In most cases, and as customarily employed, the flow nozzle will give volumes more nearly correct than those determined by pitot-tube traverse.

Discussion

[NOTE: The following discussion has been drastically condensed for purposes of economical publication. The complete discussion is on file with the P.T.C. Committee No. 10 on Centrifugal and Turbo-Compressors and Blowers of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.—Editor.]

J. E. WATSON.[2] Mention is made of the well-known fact that an evasée stack at the outlet of a fan does not increase the total efficiency. As a discussion of the evasée or streamline fan outlet was not relevant, the author did not cover this fully, and it should be pointed out that the total efficiency referred to is that of the fan based upon the fan-test code and not the total efficiency of the entire fan circuit. Varying with the type of fan used and depending upon the outlet velocity, the actual static efficiency of the entire system may be improved considerably by the use of the expanding or streamline chimney on the fan outlet, due to the efficient conversion of dynamic pressure to static pressure.

SANFORD A. MOSS.[3] The computation which the author gives of a hypothetical square wave, as shown in Fig. 1, is well known, but the rest of his mathematical analysis and all of his practical

[2] Chief Engineer, Prat-Daniel Corporation, New York, N. Y. Jun. A.S.M.E.

[3] Mechanical Engineer, Thomson Research Laboratory, General Electric Company, West Lynn, Mass. Mem. A.S.M.E.

analysis are novel as applied to air flow and seem quite accurate. The writer has had two striking illustrations of the phenomenon discussed.

A liquid tachometer was used for measurement of speed of a 500-kw turbo-generator, with a long helical-spring flexible-drive shaft. By pressing a lead pencil against the tachometer shaft while the turbo-generator was at full speed, the speed of the turbo-generator was shown by the tachometer reading to be increased about 10 per cent. Of course, the friction of a lead pencil could produce no such effect on the rotor of the turbo-generator. What happened was that the friction on the tachometer shaft made the helical-spring flexible shaft wind up and then let go periodically. This meant that the tachometer itself was operating with a pulsating speed. The tachometer reads the pressure produced by its impeller, which varies with the square of the speed, so that the tachometer reading gave the square root of the mean square of the speed, instead of the mean speed. The tachometer reading was thus greater than the actual shaft speed for exactly the same reason that an impact tube gives the error with pulsating flow which the author cites.

About 25 years ago, the writer made a test on a displacement blower with perceptible pulsations, with a short length of pipe and a nozzle, at the end of which was an impact tube. The object of the test was to measure the actual delivery of the displacement blower, so as to find by comparison with the theoretical displacement the volumetric efficiency, with the idea of demonstrating the desirability of substituting a centrifugal blower which would not have a volumetric efficiency loss. Previous experience had indicated that the volumetric efficiency was around 80 per cent. However, the test showed a volumetric efficiency of 105 per cent, and the substitution of a centrifugal blower for the displacement blower was not made. It was years before it was realized that the flow measurement was subject to the error which the author discusses.

C. J. Fechheimer.[4] That errors may arise in measurements of air volumes when pulsations are present is well known, and it is timely that false conclusions in fan testing be called to attention. It is believed that when the frequency of pulsation is fairly rapid, as indicated by Figs. 10 and 11, accurate measurements may be made with an electric thermal volume meter. This device, also known as a Thomas meter, consists essentially of an electrically heated element that warms the air and electric thermometers which measure the temperature rise of the air. The air volume can then be computed from the measured loss in the heater, the air temperature rise, and the specific heat and density of the air. There are certain precautions which should be observed with this device which are covered in another paper.[5] There are many advantages which this device possesses, such as the small pressure drop therein, and one meter is suitable for a complete curve of fan performance.

A number of years ago, while making a study of ventilation of alternating-current electrical machinery, the writer had a device built which in principle is similar to Fig. 5. A brief description is given in another paper.[6] In Fig. 10 in that paper a record of the pulsations of pressure is shown, giving the main pulsations and harmonics due to the presence of teeth and slots in the stator of a salient pole alternator. No direct use was made of the data, as means for calculating pressures, air volumes, and their distribution in a machine were obtained by mathematical deduction and empirical constants, but the records assisted toward securing a physical picture of the air-flow phenomenon in that type of machine.

R. D. Madison.[7] Some of the conclusions of the paper are not sufficiently proved by the data offered. Too few data are given and they are not sufficiently correlated. In Figs. 6 and 7 the relative point of rating is not given. One must assume that the fan speed is the same as for test curve of Fig. 8; then for 0.6 in. static pressure, which is beyond the plotted results, the inference would be that the fan is operating near free delivery. Table 1 is decidedly incomplete for a paper of scientific value. No fan speeds are given, no velocity pressures, no indication as to the relative points of rating or even if they are on the same basis, and no values of a/S to prove that where the percentage of error was small the value of a/S was likewise small.

Fig. 6 is no doubt given to show how large the wave amplitude is in comparison with the average velocity pressure. There is no actual proof that there is a velocity pulsation. The wave shown is of the total pressure, and one must subtract from it the static pressure—a pressure which the author himself says is dampened by the small pitot-tube holes and "therefore to be considered only as an average, not as a record of the wave." The author should have used a type of pulsometer similar in principle to that used by Judd and Pheley,[8] in which the diaphragm separates two air-tight chambers and the true velocity-pressure wave is given by the simultaneous difference of the static and total pressures on opposing sides of the diaphragm. If the static and velocity-pressure pulsations are of the same frequency, they may be additive or subtractive depending on the phase angle, or they may not be synchronized at all. In either case a simultaneous differential reading would eliminate this chance of error. Although from general physics one would expect the velocity-pressure amplitude to be only slightly higher at the nozzle than at the pitot-tube station in the duct when the velocity of air is small compared with the velocity of sound, Figs. 6 and 7, for the reason given, do not provide data from which "the amplitude of the wave appears to be substantially the same."

The author infers that the big discrepancies between the two methods of test and reported in Table 1 are due solely to pulsation. Fan No. 13 shows 18.3 per cent error, which according to the curve of Fig. 4 corresponds to a value of $a/S = 1/8$. This would represent a condition where the maximum velocity is $17/9$ths and the minimum $1/9$th of the average velocity—a rather severe type of flow leaving a centrifugal fan.

Again, in referring to Table 1 the author states that "no specific conclusions can be drawn from these results as to the cause of pulsation." It would seem that this very fact would lead the author to look for some cause of vibration other than velocity pressure, which, as has been mentioned, may not have been correctly interpreted by the pulsometer used in the tests. Should not static pulsations be considered? Could not noise have complicated the results, particularly as the special pitot tube used had a large bore with short connections?

The author is correct in saying that the ordinary gage does not correctly interpret pulsating flow. The gage is actuated by pressure which is proportional to the square of the velocity. If there is pulsation, the average pressure as read by a gage will always be greater than that corresponding to the true mean velocity. If the frequency is low, the gage will probably show the fluctuation and the observer will estimate the average pressure. If the frequency is high, the gage will likely not fluctuate. The error is only great when the value of the amplitude S is large

compared with a, the minimum pressure, as the author points out.

Fig. 9 shows a recommended test set-up. One cannot see how in a delicate test such as this the author can suggest a cone-throttling device which is sure to cause a high-velocity region to be set up in the large drum preceding the flow nozzle. A more uniform throttling device would seem to be more in order. As the set-up would be expensive for general approval tests and as these are becoming more and more common, any new code should simplify such procedure rather than complicate it.

To sum up, the author's conclusion 1, that a variation in velocity can exist, is valid. Conclusion 2, that the average velocity pressure is higher than the corresponding average velocity, is also true if a velocity pulsation does exist. Conclusions 3 and 4 are not substantiated by the data presented. The author may believe these conditions to exist, but the data presented are insufficient to cause any one to arrive at the same conclusions as the author. If the author has data not submitted which will show that velocity pulsation can be definitely measured and that it accounts for the discrepancy between pitot-tube traverse and nozzle tests, it should be included. The subject is of general interest and should be printed in more complete form so that it can be more intelligently criticized or approved. It does not seem that it would be a difficult matter to construct a pulsometer to be used in obtaining a correction factor for the standard pitot-tube traverse and save the tremendous expense of duplicate tests on commercial fans. At least, it should be further investigated before a radically different code is passed upon.

P. H. HARDIE.[9] This paper brings to the front again the discussion of the relative accuracy of pitot-tube and nozzle measurements of air quantities in connection with fan tests. The writer thinks that any one who is at all familiar with these two methods will concede that the nozzle measurement is more reliable and therefore preferable. The paper, however, shows the pitot tube in a more adverse light than is actually the case. If there was no explanation, other than pulsating flow, for differences in volume measurements as great as 16 or 18 per cent (shown in Table 1), the pitot tube would be considered so unreliable that it would be discarded. Due to the lower cost of the pitot-tube test, many engineers will consider carefully the relative accuracy of the two methods before eliminating the pitot tube as a test instrument.

The vibragraphs shown are interesting, but do not seem to prove the author's contention that large errors in pitot-tube volume measurements are due to pulsating flow. From measurements of the velocity pressure wave in the vibragraph, Fig. 6, the average value of a/S for the 87 cycles shown was found to be 6.3. This ratio gives an error due to pulsating flow of $^1/_2$ per cent instead of 7 per cent as reported for this test and shown in Fig. 8. The relative amplitudes of the pulsations in the other vibragraphs shown are even smaller.

In order to illustrate the extremely large amplitude of the velocity pressure wave necessary to produce an error of 7 per cent, graphs were made of a velocity sine wave with a ratio of $a/S = 0.8$ and of the resulting velocity-pressure wave. If the velocity pressure wave were sinusoidal, the error for the same amplitude would be about 6 per cent, and if it were triangular, the error would be only 4.5 per cent. The error for a triangular wave is expressed by the following equation:

$$\frac{\text{Per cent error}}{100} = \frac{3S'\sqrt{a' + S'}}{\sqrt{(a' + 2S')^3} - \sqrt{(a')^3}} - 1$$

The primed symbols refer to the dimensions of the velocity pressure wave corresponding to those for the velocity wave.

The author, while reporting the fact that the static pressure fluctuates as well as the impact pressure, apparently gives no consideration in this paper to the resulting higher measured static pressure. Since the velocity pressure is the difference between impact and static pressures, this higher static reading would at least tend to reduce the apparent error due to pulsating flow and might even cancel it. By "apparent error" the writer means the error computed from vibragraphs which give only the true wave shape for the impact pressure. The slightly higher static pressure itself would have but little effect upon the efficiency.

Poor distribution of the air flow at the pitot traverse station and duct velocities too low to be accurately measured are the causes of 95 per cent of the errors obtained with pitot tubes. It should be evident to those making a test that accurate results cannot be expected under such conditions, and therefore the difference obtained between the pitot and nozzle measurements is no criterion of their relative accuracy when so measured.

The writer wishes to disagree with the author in his contention that propeller fans cannot be accurately tested on the outlet end. A test was made on a two-blade propeller fan with a pitot tube and nozzles of three different sizes. Good agreement between the two methods was obtained, the nozzle measurement giving only slightly higher flows. A thorough investigation was made to determine if any peculiar conditions of flow existed, such as spin, that would cause erroneous results, but none was found. It was discovered, however, that the standard pitot tube used would read a slight positive static pressure in a stream of air 4 ft. from the outlet of a nozzle, and that the higher the velocity, the greater the error. This characteristic of the tube may account for the lower flows obtained with the pitot tube.

E. L. ANDERSON.[10] A review of investigations published covering the study of pulsation in air flow reveals a considerable collection of data upon reciprocating compressors. The published work on pulsation flow from low-pressure centrifugal fans rests in this paper, in which several of the phenomena remain unexplained. Application of Hodgson's formula of the sine wave in explaining several noted excess readings in pitot velocity is excellent, with the reservation that sound waves are complex, and, further, rarely are true sine forms, and that the "upstream cavity is larger than the downstream cavity, with the result that when a change of pressure occurs the pressure will rise and fall most quickly in the downstream cavity, thus exaggerating the readings" (Hodgson).

The basis for the major deductions responsible for the proposed code lies in the work performed upon reciprocating compressors. A further study was made by us upon a system of approximately the same size of ducts, and design analogous to the proposed code, substituting a centrifugal fan in place of the reciprocating compressors. Means were provided for controlling both amplitude and frequency of pulsations, and measurements of waves were made acoustically. Curves were plotted giving the pitot-tube pressure variations as related to frequency variations with constant total pressure at nozzle and giving the pitot variations as functions of amplitude at three different selected frequencies. The results fail in confirming results on centrifugal fans as duplicating those obtained in reciprocating compressors. The curves of the tests made indicate:

(*a*) That all pressures are affected by frequency as well as amplitude.

(*b*) Errors of static pressure readings due to pulsation.

(*c*) Relative effects of pressure variations with frequency and amplitude may be compensating or cumulative.

[9] Test Engineer, Brooklyn Edison Company, Brooklyn, N. Y. Assoc-Mem. A.S.M.E.

[10] Research and Development Department, American Blower Corporation, Detroit, Mich.

(*d*) Error in all pressures may be either greater or less than smooth flow conditions.

(*e*) There is an indication of reflected system resonance.

Other curves plotted show the relative pressure readings at pitot and nozzle referred to a fixed nozzle velocity from a large-volume chamber which has been very heavily treated acoustically. The flow-nozzle static pressure smooth flow for upstream was 0.60 in. water gage and for downstream was 0.116 in. water gage.

Following the suggestion of reflected system resonance a test was run on a pipe of estimated period. Indications are of such a definite nature as to warrant further determinations regarding this condition.

The accuracy of a system of fan test is dependent upon three factors of pressure: total, static, and velocity. Providing the velocity pressure is accurately determined, it is essential that either the total or static be as accurately determined in order to compute the air-horsepower consumption of the fan, and, further, the relative position of the fan operation on a given system or systems. The proposed code is based upon the following:

1 That data compiled relating to reciprocating high-pressure, low-frequency pulsations may be applied to centrifugal low-pressure, high-frequency apparatus.

2 That the pulsation is substantially a sine wave.

3 That pitot-tube error is a function of wave amplitude only.

4 That static pressure be considered as an average and true reading due to throttle effect of pinhole orifices.

5 That pressure discrepancies are a function of wave amplitude only.

6 That pressure discrepancies are always in excess of pulsationless flow.

7 That nozzle flow may be corrected by applying the formula as given by Hodgson, and as further indicated by Andrae and Diedrich, for amplitude only.

8 That acoustic period of system has no effect on pulsation.

9 That the accuracy of nozzle measurements exist in Hodgson's suggestion of conversion of static to velocity pressure at nozzle, and throttling upstream from nozzle.

As related to the suggested physical design of proposed test system, the following is presented:

1 The pressure frequency amplitude of such data produces such dissimilar conditions as to preclude its application without thorough search for actual similitude.

2 Pulsation wave is not a true sine wave. Any correction factor based upon the true sine wave will be in error.

3 It is shown experimentally that pitot-tube error is caused not only by amplitude, but also by frequency, and that the effect of frequency may equal the amplitude error. The error may be either compensating or cumulative.

4 It is further shown experimentally that static pressure reading is rarely if ever accurate under pulsation flow, and that under some possible conditions, the error may transcend that of the impact tube.

5 All pressure discrepancies are a function of wave amplitude and frequency.

6 Pulsation error may be either above or below the pulsationless flow.

7 Nozzle flow is affected by amplitude and frequency.

8 Period of system may affect pulsation.

9 This assumption is confirmed as stated by Hodgson.

HENRY F. SCHMIDT.[11] The author has called attention to an important possible source of error in the testing of fans and blowers. Further study of the pulsations produced by such apparatus should be conducted, if possible, to determine their source.

The writer wonders, however, if for practical purposes the errors observed do not exist principally in the pitot tube and the usual method of determining static pressure. A number of years ago, in attempting to study the velocity distribution and determine the losses in a free vortex or whirl chamber of a blower where the velocities were of the order of 600 ft per sec, various forms of pitot tubes were employed, but the results obtained were so obviously in error that all forms of pitot tubes were abandoned and the readings were taken with an impact tube.

At this time the writer found that the Anaconda Copper Company had had a very extensive investigation made of pitot tubes in connection with determining the discharge from the big stack of the smelter at Great Falls, Mont. This investigation, which included the usual forms of pitot tube, also covered experimental work on static ends of the plate type, having holes of various sizes and distribution, as well as slots. This investigation showed that none of the static ends, either of the conventional pitot tubes or of the special forms investigated, indicates the true static pressure, all of them having errors which are a function of the velocity of the stream in which the tube is inserted.

More recently the writer had occasion to demonstrate the inconsistency of the static readings obtained with the standard pitot tube recommended by the American Society of Heating and Ventilating Engineers. By inserting the pitot tube in a jet issuing from a Moss nozzle with a quite smooth flow, it was observed that whereas the pressure in the jet must be atmospheric, the static end showed either a plus or a minus error, depending upon the velocity of the jet. This might be attributed to standing waves in the jet. This assumption, however, is precluded by the fact that with a constant jet velocity, the pitot tube was moved slowly along the axis of the jet and the error remained substantially constant, decreasing very slightly with increased distance from the nozzle.

A Prandtl tube was tested in the same jet at the same velocities and showed a fairly uniform error independent of the velocity and of the position along the axis of the jet. For this reason the Prandtl tube is superior to the A.S.H.V.E. tube, even though it does not give the correct static pressure. Because of these experiences, the sensitiveness to disturbances in flow and alignment with the stream lines, and the discrepancies between nozzle and pitot-tube measurements, which are mentioned in his paper, the writer believes that the pitot tube should be discarded as a test instrument for the measurement of volume or static pressure.

Since 1909 the writer has employed only nozzles for determining volume, measurements being made either at the entering or discharge side of the blower, and in some instances both at the inlet and discharge. In such cases, the writer has not observed differences exceeding 1 per cent in the two measurements. In making nozzle measurements, the writer has always employed a piezometer ring having a large number of small holes, as this undoubtedly gives more reliable results than a single opening in the side of the duct. If for some reason it is impossible to use a piezometer ring, at least four openings in one plane of the duct should be connected to a single manometer.

While the nozzle developed and recommended by Dr. Moss is unquestionably the ideal form for small nozzles used in testing high-pressure blowers or compressors, this form of nozzle is prohibitive because of cost for the testing of large blowers.

While the writer agrees with the author that pulsations do exist and may in some cases be the cause of serious error, based on broad experience with both pumps and blowers of exactly similar design and the use of piezometer rings for measuring pressures, the writer wonders whether the discrepancies do not possibly exist almost entirely in the pitot-tube method of measurement.

In regard to the suggested method of using steam coils for

[11] Consulting Engineer, Westinghouse Elec. & Mfg. Co., Philadelphia, Pa.

heating air as a check method of determining volume, the writer would expect far more serious errors by this method than in the case of a pitot tube, as it would be necessary to accurately determine the quality of steam entering the coil in order to be able to calculate the heat given up by the condensate, which is weighed. The heating method is open to many objections, and there are many possible sources of error such as radiation, accuracy of measurement of the heat input, and the correct measurement of the temperature rise of the air. If any heating method of determining the volume is to be employed, the writer believes it preferable to employ electric heating elements, which should be in the form of copper strips properly braced to prevent vibration, and the thermocouple elements must also be so supported to prevent vibration, since it has been found in the laboratory that serious errors in the temperature measurements are observed if the wires forming the thermocouples vibrate in the air stream. While possibly such measurements can be made with a high degree of accuracy under laboratory conditions by people skilled in this method, it has many pitfalls for the casual user.

The author has stated that, contrary to expectations, six-bladed propellers do not show less pulsation than those with two blades, thus indicating that the decrease of efficiency with increasing number of blades is not attributable to pulsations. Further evidence to this effect is shown by the writer's tests on $2^3/_8$-in. propellers pumping water and on 12-in. propellers in air. While the efficiencies are not the same, the percentage differences in efficiency for each additional blade are nearly alike.

The writer attributes the decrease of efficiency to the increased number of edges and the fact that the friction on a surface decreases with increased distance from the leading edge. Thus the surface friction on two surfaces each 2 in. wide is greater than that of one surface 4 in. wide. According to the hydrodynamical theory for flow in an ideal fluid, an entering edge causes no resistance, but the writer does not believe this is true for air or liquids with which we have to deal. For this reason, the writer has termed the observed efficiency differences "the edge loss," whatever that may actually mean.

Though it may not be possible to design blowers which do not produce pressure pulsations of appreciable magnitude, such pulsations as do exist can be damped almost completely by the use of a duct constructed of perforated plate surrounded by a space of 2 or 3 in. radial depth filled with cotton waste, enclosed in a non-perforated shell similar to the "Burgess" muffler, the perforated section of duct being 10 diam or more long, depending upon the amplitude of the disturbances which exist at the blower outlet. Some research work along this line should be undertaken to fix some rules for determining the length of muffler required to damp pulsations to a negligible value. Such mufflers are also quite effective in reducing noise.

Possibly such a dampening means should be employed in testing to avoid any effect of pulsations on the readings.

J. M. Mayoral.[12] The author presents an interesting explanation of the inconsistencies sometimes experienced in the testing of centrifugal fans. His use of the pressure-fluctuation indicator opens up a method of investigation that may eventually furnish a solution of the problem. The paper shows that in measuring the output of a centrifugal fan much more reliable results can be obtained by using a nozzle exhausting to the atmosphere at a relatively high velocity than by using a pitot-tube traverse in the duct. It also shows that if the results of the pitot-tube traverse and the nozzle determination of volume agree, it is an indication that any velocity pulsations in the flow are negligible.

The vibragraphs demonstrating that the wave form of the impact pressure as measured at the pitot-tube station is similar in shape and amplitude to that measured at the mouth of the nozzle are interesting. In order to get a reliable indication of what is happening in the duct, however, it will not be sufficient to have vibragraphs of the impact pressure only. Study must be made of the variation of the static as well as the impact pressure in order to determine the form of the velocity-pressure wave. The author admits that the static pressure in the duct is variable and that the wavy static pressure line in Fig. 6 does not show the true wave form.

C. E. Peck.[13] This paper has material of especial significance for any one concerned with methods of accurately determining fan performance. In all probability, the presence of pulsation as a factor which seriously affects fan-test procedure has been neglected to a great extent in the past and explains in many cases why investigators may not independently check the performance of the same fan when two different methods of measuring volume are used. It also is of special importance to note that the standard test code in its present form is not complete enough to provide for elimination of excessive errors in fan testing when the pulsations produced by the fan are of sufficient magnitude to make the results of the pitot-tube method difficult to interpret correctly. As mentioned in the paper, the presence or absence of errors due to pulsation can at the present time be best determined by making two volume determinations—one by the usual pitot-tube traverse method and one by a nozzle determination at a higher velocity, close agreement implying that only small errors are present. This method uses the nozzle as the standard of reference. In some extreme cases, the nozzle result may give considerable error due to pulsation. The most desirable solution would be the development of a simple, compact indicating instrument which could be placed in the duct and would measure the amplitude of the pulsation. An approximate knowledge of the amplitude and the average velocity would be enough to determine the error due to pulsation, as in Fig. 4 of the paper. This would simplify and make accurate the testing of the fan in systems outside of the laboratory and the well-equipped test floor. The advantage of the pitot-tube traverse method is the ease with which it can be adapted to all types and sizes of fan testing set-ups, and at the same time provide a means of determining velocity and static pressure simultaneously. This advantage is lost when flow nozzles are used because of the large number needed to cover the size and volume range. Since in any fan test the pitot-tube readings cannot be interpreted correctly until the magnitude of the error due to pulsation is determined, it is important that a simple auxiliary instrument be devised to measure pulsation amplitudes if the pitot-tube method is to survive in the standard method of testing fans.

Another more fundamental approach to the problem of pulsation magnitude, but probably much more difficult to execute, would be to make a study of the amplitude and energy in the pulsating wave as a function of the fan design (type, speed, capacity, size, etc.) and its accompanying duct work. Some general conclusions can be arrived at as more fans are checked experimentally for pulsation errors. The observation noted by the author, that the pulsation error is greater with larger outputs, has been checked recently by some tests at the Westinghouse Elec. & Mfg. Co. in connection with the ventilation of railway motors.

A single-inlet centrifugal-type blower was used to supply air through a 2-ft-diam duct to a railway motor, the duct being about 70 ft in length. Volumes were measured simultaneously by means of a thermal volume meter (which measures mass rate of flow) and two types of pitot tube—the standard type used in the

[12] Assistant Test Engineer, Brooklyn Edison Company, Brooklyn, N. Y. Jun. A.S.M.E.

[13] Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Jun. A.S.M.E.

fan test code and the spherical-head Prandtl type. For those types of motors requiring low static pressures (2 to 4 in. of water) for about 10,000 cu ft per min volume, the two methods of volume measurement checked consistently within $1^1/_2$ per cent. The two different type pitot tubes checked within 1 per cent. For these tests, the thermal volume meter was located about 22 duct diameters from the fan and the pitot-tube station about 26 diameters from the fan. For the same locations and the same volume, but for higher static pressures (7 to 9 in. of water) obtained by increasing the speed of the blower, both pitot tubes checked each other, but differed from the thermal volume-meter measurement by giving 10 per cent higher volume. For the same volume and pressure, another pitot-tube traverse taken $7^1/_2$ duct diameters from the fan (standard distance) gave a volume 13 per cent higher than at the station 26 diam from the fan, or 23 per cent higher than that obtained by the thermal volume meter. Although these tests are not as yet complete, some tentative conclusions are:

(1) The variation in pitot-tube readings compared to the thermal volume meter from the lower to the higher static pressures indicates that the pulsation has become a serious factor at the higher pressures.

(2) The upward variation of the pitot-tube reading at the two stations indicates higher pulsation errors at a point nearer the blower. An exceedingly long duct would be needed to eliminate pulsation errors. In these tests, assuming the thermal volume meter as a standard of reference, even 26 diam was not enough to eliminate excessive pulsation errors.

(3) The thermal volume meter does not seem sensitive to the pulsation magnitudes which affect the pitot tube. More tests will have to be made before this conclusion is entirely justified. The results obtained by placing the volume meter closer to the blower ($7^1/_2$ diam) have not yet been made at the time this is being written. It seems reasonable to expect that the volume-meter readings (energy input to heater and air temperature rise) would be little affected by pulsations of the order encountered in fan work. The temperature rise of an air particle going through the heater coils varies approximately inversely as the velocity to the first power; hence, the average temperature rise of the particle is the same whether the air is pulsating or not. Only in cases where the pulsation would be of enough magnitude and vibrate in such a manner as to produce non-uniform distribution and "back flow" would the volume meter accuracy be affected. Further experimental evidence as to the accuracy of the volume meter under pulsating conditions must be obtained before definite conclusions as to its correctness can be made.

Figs. 6 and 7 of the paper bring up several questions. Is not the measurement of static pressure by means of the static holes in the pitot tube subject to errors of the same order as those encountered in the measurement of the total pressure (velocity pressure plus static pressure) when such measurements are made within a duct? Fig. 6 shows that a vibration of appreciable magnitude exists at the static pressure holes. This probably gives higher average static pressure readings than the actual average static pressure. Since the velocity head is not measured directly in this case, but can only be determined by the difference between the total pressure and the static pressure, the error in the average velocity head is affected by errors in measurement of the two components by which it is determined. It seems to the writer that a high value of a/S is not the only criterion of correctness. The flow-nozzle method, as described in Fig. 9, enables a pitot determination at the exit of the nozzle to be made, at which the static pressure is zero, and in which case the impact pressure corresponds to the velocity head directly; hence, no error is introduced due to possible inaccuracies arising from measurements of static pressure. It seems reasonable to assume that for this reason, as well as for a higher value of a/S, the flow-nozzle determinations of volumes are more accurate and consistent when the flow is pulsating. The question also comes up as to how the static pressure is to be determined accurately under pulsating flow conditions if it is necessary to determine the volume independently by means of a flow nozzle.

Some evidence as to whether the measurement of static pressure is a contributing cause to the different results obtained with the flow nozzle versus pitot-tube traverse inside a duct could be obtained as follows:

A pitot-tube traverse could be obtained inside a duct containing pulsating flow with appreciable values of a/S and static pressure. A similar traverse could be obtained at the exit of the same duct where the static pressure is zero, thus maintaining a constant value of a/S, but varying the static pressure for the same average velocity-pressure determination. If the average velocity pressure at the duct exit checked a nozzle determination more closely than that obtained inside the duct, then part of the error is due to static-pressure measurements.

If such results were found, then the standard test code would have to be revised still further, and the testing rig made such that static pressures could be measured more accurately. This would probably mean larger inlet or outlet boxes adjacent to the fan constructed in such a way as to damp out pulsations at the point where static pressures are to be measured.

Author's Closure

Several of the discussions mention a possible difficulty in measuring static pressure with a pulsating flow. Detailed comment on such a possibility would be highly controversial and at the present time fruitless and indeterminate.

The use of the free nozzle and impact tube to determine fan volume, which for accuracy seems to meet with general approval, permits basing of test results on the readings of impact tubes only. Another impact tube is used in the fan duct to measure total pressure. The fan static, if wanted, is obtained by calculation from the nozzle volume and the fan-outlet area.

The static tube is used only for the differential velocity pressure in the fan duct, and the resulting volume as calculated provides a check on the nozzle volume. In the event of large differences in the two volumes, it is recognized that even the nozzle volume may be too high, and certain methods of approximation are suggested to approach a more nearly correct result. In this method of test the function of the static tube is solely to indicate the presence of pulsation. Apparently none of the commentators objects to its use for that purpose.

It is well known that flow pulsation increases the loss in head due to friction. The amount of this increase is directly proportional to the increase of the indicated velocity pressure above the velocity pressure for uniform flow. It is important, therefore, to know whether pulsation is present, particularly if pulsation can persist through long lengths of duct.

Mr. Peck's contribution contains new and valuable information showing that serious pulsation has carried for at least 26 diam of duct length.

The confirmation from their own work, some of it apparently antedating that of the author, by Dr. Moss and Messrs. Fechheimer and Peck is valuable and necessary.

In Mr. Madison's opinion the author's presentation is incomplete. The paper proceeds from inference based on known facts to a rational hypothesis which test results confirm with reasonable quantitative exactness. All pertinent data are given. The theory is explained, and a suggested method for avoiding the test error is presented, and with sufficient completeness to enable any one familiar with the art to undertake a similar investigation. Such procedure seems to accord with the accepted scientific method. Fig. 6 was taken at the largest nozzle-

volume point of Fig. 8. A speed conversion, with which Mr. Madison is unquestionably familiar, to comply with certain of our laboratory rules of standardization of curves was introduced in the curve.

Mr. Madison's opinion that measurement of a fluctuating velocity pressure is a simple matter must be answered at length to avoid the misleading of other experimenters. Any one interested should read report No. 320 of the National Advisory Committee for Aeronautics, which describes experiments leading to a successful quantitative diagram of a pulsating static. The work done by Professor Judd and Mr. Pheley was at the low frequencies of reciprocating compressors. The ingenious instrument they used is not applicable to the high frequencies encountered in a fan discharge.

The symmetrical throttling cone, the distance to the nozzle, and the diameter of the nozzle mouth are all in accordance with accepted practice for measurement with free nozzles. The results have been checked by nozzles directly on the end of 10 diam of straight duct.

Mr. Madison and Mr. Hardie both find difficulty in attempting to conceive of a kind of flow that would account for the large errors found by comparative tests. The author believes that the evidence of the quantitative results of Table 1 in the paper is the best answer to their opinions.

Mr. Hardie's quantitative analysis of Fig. 6 is due to a misunderstanding of the diagram. The paper clearly states that the static line is an average, and so there are no instantaneous velocities to be evaluated. The author disclaims any quantitative value for even the impact line. The air column leading to the instrument will decrease materially the recorded wave amplitude. Considered in this light, the diagrams seem not unconvincing.

The suggestion made by both Mr. Hardie and Mr. Schmidt that inaccuracies of the standard pitot tube are responsible for the errors is controverted by the results reported by Mr. Peck, whose findings are in accordance with those of other experimenters.

Mr. Anderson apparently considers precautions necessary to avoid pulsation error, but is concerned also about static-pressure difficulties, which were dealt with in the opening paragraph of this closure. The remainder of his discussion deals chiefly with certain suggested methods of approximation to be used when severe pulsation is indicated and which are more applicable to the proposed new code in which these suggestions appear than to the paper itself.

Referring again to Mr. Peck's discussion, the author hopes that Mr. Peck will continue his investigation. A 70-ft duct, 35 diam, will enable him to search out various matters that are not apparent in the usual length of test duct. The author wishes further that Mr. Peck might find it possible to use a flow nozzle at the end of the duct as an additional measurement. This volume would be of great help in deciding on the reliability of the electrical method and might further, in combination with the pitot tube and the electrical method, give experimental information as to nozzle-volume approximations when extreme pulsation is indicated.

Performance of Modern Steam-Generating Units

By C. F. HIRSHFELD[1] and G. U. MORAN,[2] DETROIT, MICH.

C. F. Hirshfeld

This paper is the final report on a study made of the performance of 250 large steam boilers over a period of three years. The results of the first year's study were reported at the 1929 Annual Meeting of the A.S.M.E., and a summary of the full three-year period was presented at the 1931 Annual Meeting. The study was requested by the Central Station Power Committee of the Power Division. The primary object was to study boiler outages and their causes and the effect of such factors as severity of use, design, fuels, and methods of firing on boiler reliability, in the hope that a yardstick might be obtained by which the individual operator could measure the performance of his own units and predict the probable availability of new designs. The data obtained from each unit are presented, together with some comparisons of types and classes of unit. There also is a discussion of primary causes of boiler shutdown, which has not appeared in either of the previous papers.

G. U. Moran

STEAM-GENERATING EQUIPMENT has received its share of attention in technical literature and discussion, with respect to most of the factors affecting its design and operation. The quite considerable increase in thermal economy, which has been attained during the past two decades, has been widely discussed. The former "boiler" has evolved into that complicated structure we now know as the steam-generating unit, but the development was by no means made blindly. The effect on thermal efficiency of each addition to and refinement of the "boiler" has been determined to such a degree that the designer may predict with confidence the thermal performance of his creation. This knowledge has made it possible to weigh investment cost against probable savings and to define limits beyond which an increase in efficiency would be overbalanced by a disproportionately large increase in initial cost.

But low investment is not of itself a complete criterion on the dollar side of the picture. A large investment which can be used for, say, 80 per cent of each complete year of the life of a plant may represent a better economic solution than a smaller investment made to accomplish the same result, but usable only during, say, 50 per cent of the entire year. In other words, the extent to which equipment can be kept in as continuous service as existing conditions indicate to be ideally desirable is also an important measure.

Thermal efficiency is comparatively easy of proof. Investment made is merely a question of fact. The performance factor, however, is a question of experience, and any one individual's intimate experience must necessarily be limited to a comparatively small number of installations. It results that while there is available a wealth of information concerning thermal efficiencies and first costs of steam-generating plants, there is very little information about the extent to which various features of design influence the ability of those plants to produce when and as required.

This fact was appreciated by the Central Stations Committee of the Power Division, A.S.M.E., when it requested the authors to make this investigation and to provide if possible a yardstick of normal values by which the individual operator might determine whether his performance was good, bad, or normal.

The study was started in July, 1928, with the collection of daily operating data from 186 boiler units located in 50 plants well scattered throughout the United States. The analysis of one year's records, which was presented as a paper[3] before the Power Division at the Annual Meeting, December, 1929, showed that, if significant results were to be obtained, the study should be continued over a longer period and a larger number of units should be included. The present paper therefore represents an investigation of 250 units in 61 stations, covering the three-year period between July 1, 1928, and July 1, 1931. A progress report was made at the Annual Meeting in December, 1931. It contained a general summary of the data at hand, but due to lack of sufficient time for preparation, the more detailed report was postponed and constitutes this, the final paper.

The procedure followed in obtaining the data has been set forth in the 1929 paper, together with definitions used. To conserve space the method will not be repeated here in detail. Suffice it to say that the data were collected by means of printed log sheets which were filled out by the operators themselves and

[1] Chief of Research, The Detroit Edison Company. Mem. A.S.M.E. Mr. Hirshfeld received the degree of B.S. from the University of California and the Master's degree in Mechanical Engineering from Cornell University. In June, 1932, he received the honorary degree of doctor of engineering from Rensselaer Polytechnic Institute. Until 1913 he served as a member of the faculty of Cornell University, then becoming associated with The Detroit Edison Company.

[2] Research Department, The Detroit Edison Company. Mr. Moran received the A.B. degree from Amherst College in 1920 and the B.S. degree in Mechanical Engineering from Purdue University in 1922. Since that time he has been with The Detroit Edison Company in the production and research departments.

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

[a] Abbreviations for method of firing: TG, traveling grate; Und, underfeed; St, storage; Un, unit; OG, oil and gas; UP, unit pulverizers with oil and gas; TO, traveling grate with oil and gas.
[b] Abbreviations for type of dust collector: CT, cinder traps; CC, cinder catcher; CF, cinder vane fan; EP, electric precipitator; Cy, cyclone; SN, spray nozzle.
[c] Abbreviations for combustion control: Ml, manual; SA, semi-automatic; Ce, centralized; Au, automatic.

TABLE 2 ANALYSIS OF TIME UTILIZATION OF INDIVIDUAL STEAM-GENERATING UNITS

Unit No.	Total hours	Percentage of total period: Steaming	Banked	Reserve	Crippled	Outages classified as to cause, expressed as percentage of total outage: Scheduled cleaning and overhaul	Changes in equipment	Boiler and superheater	Reheat boiler	Furnace	Stoker	Pulverizing equipment and burners	Economizer and air preheater	Ash equipment	Draft equipment	Instruments	Not chargeable to unit	Availability factor	Use factor	Unit No.

TABLE 3 INDIVIDUAL HEAT-TRANSFER RATES OF STEAM-GENERATING UNITS

Unit No.	Length of period reported, years	Total water evaporated, 1000 lb	Total steaming hours	Average evaporation, 1000 lb per hr	Average evaporation per unit of: Saturated steam surface, lb per sq ft per hr	Furnace volume, lb per cu ft per hr	Projected grate area, lb per sq ft per hr	Average heat output of boiler proper: In saturated steam, kb per sq ft sat. surf. per hr	In superheated steam, kb per sq ft sat. surf. per hr	Average heat output of entire unit represented by: Saturated steam surface, kb per sq ft per hr	Superheated steam: Saturated steam surface, kb per sq ft per hr	Superheated steam: Furnace volume, kb per cu ft per hr	Superheated steam: Projected grate area, kb per sq ft per hr	Unit No.

analyzed by a single group of men in the office of the authors. Particular attention was given to crippled periods or outages and their extent, cause, and frequency, with enough other information to give the authors some idea of the operating and load conditions to which the individual units were subjected. Design and descriptive data were also obtained for each unit studied.

Tables 1, 2, and 3 give these data for each unit separately. For convenience they are grouped according to method of firing and further subdivided into steam-pressure classes. They are ordered according to average rate of driving, expressed as kb (1000Btu) output of the entire unit per square foot of saturated heating surface. Each unit has a designation consisting of a letter or letters and a number. The letter classifies the unit as to method of firing or the type of fuel burned, as: S, stoker-fired; P, pulverized-coal-fired; OG, oil- and gas-fired. A fourth group consisting of units using coal and either gas or oil is designated by the letter M. The numbers indicate the position in the group in which the unit falls. In the case of reheat boilers, the letter R follows the firing-method designation and precedes the number. Each individual unit carries the same designation in every table in which it may appear.

At this point it might be well to insert a note of caution to the reader so that he may not be misled by mere figures. As in the first year of the study, some difficulty was encountered in appor-

tioning the reported crippled hours among the various causes. The operators were requested to give the primary cause of outage in each case, but many occasions arose in which more than one part of the unit was worked on at one time. For instance, the boiler might be shut down and crippled for repairs to the furnace, but the operators might very naturally take advantage of the opportunity to make extensive repairs to the boiler or stoker. These latter might not be in any way urgent, but would certainly tend to defer or even avoid future shutdown for such work. Also it is the practice of many operators to schedule repair work at definite intervals. This permits the maintenance crew to do the most work in the least elapsed time by working on several parts of the unit simultaneously. In such instances the operators were requested to give more detailed information, especially when the original log sheets showed an appreciable divergence from the average. By this means the authors have been able to correct much of the misleading data.

Table 4 is a summary of the operating records, with the units grouped according to steam pressures and firing methods and further subdivided according to the length of time represented by the operating records received. The figures under the heading "Group performances" are averages weighted according to the number of boiler-hours involved in each case. The method of weighting was described in detail in the progress report, under the same title as this paper, presented before the Power Division at the 1931 Annual Meeting. The figures for class performances were computed in a similar manner.

discussed point. This is shown for the units studied in Table 8. The decrease in availability due to preheat is still marked, being from 0.018 to 0.063, but not as great as that shown by the 1929 results, when the decrease was in all classes greater than 0.05. This would seem to indicate that the use of preheat is now better understood or that the degree of preheat has been reduced. At any rate the results are so consistent that it is reasonable to assume that they represent fact.

In order to show the degree of use of the various classes of steam-generating units, load-duration curves were constructed for each class. They are shown in Fig. 1. The percentage of maximum continuous steaming capacity, as given by the operators, is plotted against the percentage of steaming time. With

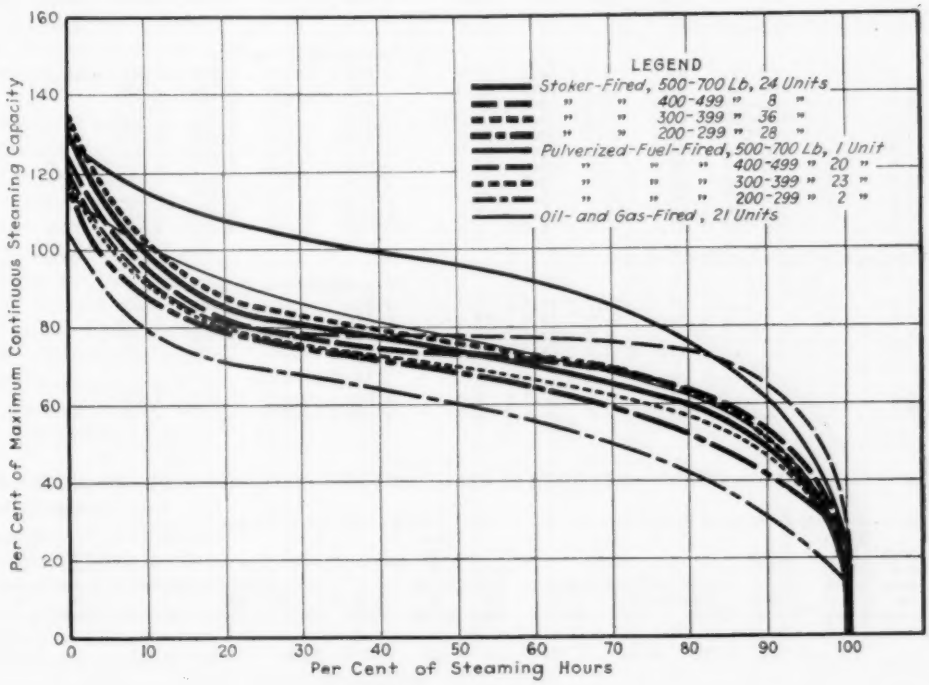

FIG. 1 LOAD-DURATION CURVES

Table 5 is reprinted from the 1931 paper (where it appeared as Fig. 2). It compares the results of the three-year study with those obtained in the first year. The 1931 paper contained a detailed discussion of the comparison, which need not be repeated here.

Further subdivision of the pulverized-coal-fired and stoker-fired groups has been made. Table 6 compares the unit and storage types of pulverized-coal firing. The availability factors first given are those taken directly from Table 2 and weighted as in Table 4. The second pair were obtained by eliminating those outages which are not affected by the method of firing and retaining only those which bear directly. At first glance it would seem that there is very little difference between the two types, but on closer inspection of the second comparison the storage type has the advantage. There is too much difference, however, in the number of boiler-hours involved to justify placing too great weight on this result. Also, the difference between high and low limits in each case is far greater than the difference between the averages.

Table 7 shows underfeed and traveling-grate stokers treated in like manner. Here again the difference may be within the accuracy of the data.

The effect of air preheat on unit availability is another much-

the exception of a group of two boilers below the average and a single unit above, the main body lies in a narrow band across the face of the chart, showing that the boilers in general were operated at approximately equal rates with respect to the standards set up for them by the designers. This in a sense bears out the conclusion arrived at after the first year's study. It was noted at that time that the apparent severity of use based on heat output per unit of heating surface had no appreciable effect on availability. Reference is made to Figs. 9 and 10 of the 1929 report. Fig. 1 of this paper indicates that boilers showing the higher unit rates of output were purposely designed for such conditions and apparently have fulfilled the intents of their designers.

The discussion up to this point has dealt with boiler outages grouped under a few necessarily large heads. Realizing that further study of these individual heads would be of considerable interest, the authors choose the three largest items charged to each unit—for instance, the stoker, furnace, and boiler or the pulverizing equipment, boiler, and economizer, as the case might be—and requested that the operators make a brief statement as to outstanding troubles and primary causes.

Table 9 is an attempt to summarize the replies and to put them in such form that comparisons may be made between pressure and

[a] Certain numbers given in Table 4 are followed by a question mark. Inspection will show that they represent extraordinarily low values for crippled hours. It is believed that the low values either result from an unintended interpretation of definitions or that the age of the units is not sufficient to have brought about a representative average performance.

TABLE 6 COMPARISON OF AVAILABILITY FACTORS OF PULVERIZED-FUEL-FIRED UNITS OF THE UNIT AND STORAGE TYPES

Type	Total hours reported	Crippled hours	Crippled hours not directly chargeable	Net crippled hours	Availability factor
Unit	234,113	36,198	25,833	10,365	0.955
Storage	828,153	112,887	78,112	34,775	0.958

fuel classes. Some of the finer detail has of necessity been omitted, as it would serve only to confuse, without bringing to light anything of general applicability.

In every instance there were several units for which the outages were classed by the operators as normal or expectable. This was particularly true of the older, well-tried boilers. These are not included in the table for obvious reasons. The causes listed, therefore, may be considered as the result of experimentation with new ideas, contingencies, inadequate or faulty design, peculiar local conditions of fuel and operating methods, or a combination of several or all of these factors.

The three or four largest items of outage are presented for each class of unit and are arranged in order of magnitude. They appear in the table in the column headed "Part of unit crippled." Under the next column, headed "Reason for outage," are listed the causes of shutdown as furnished by the operators.

No attempt was made to list them in order of importance or magnitude as the individual lengths of time are not available. They are considerably abbreviated, but every effort was made to preserve the intended meaning of the operators.

In examining Table 9 it will be noticed that, with one exception, the furnace, stoker, boiler, and superheater were the greatest offenders in the stoker-fired classes. The exception was the large outage due to cleaning dust-clogged air preheaters and excess slag accumulations from the boiler tubes. This latter probably would have resulted in crippling the boiler proper if left long enough, so it might with reason be termed an incipient boiler outage, if not an actual one.

The stokers seem to have had their greatest difficulties with preheated air and the wrong type of coal. In each pressure class one of the largest stoker outages was due to burned parts, caused by preheated air in the two higher pressure classes, and low-ash, low-volatile coal in the 200–299-lb class. No details were given for the 300–399-lb class. As the 500–700-lb class units are fired with traveling grates and the 400–499-lb class use underfeed stokers, no evidence is given as to the relative ability of the two types to resist preheat.

Plain refractory walls were the cause of considerable crippled time in all classes but that of 400–499-lb. In this class 8 of the 12 boilers have furnaces which are almost entirely water-cooled. In many instances slag accumulation and erosion hastened the failure of the plain walls, which was to be expected in view of the large stoker outages due to coal conditions.

Tube replacements and valve repair constituted the greater part of the boiler and superheater outage, with three instances in the 300–399-lb class of warped elements in radiant superheaters. Coal conditions again appear to have considerable effect on performance, as many operators reported excessive slag deposits on tubes and overworked or ineffective soot blowers in cases where the amount of ash entrained with the furnace gases was abnormally high.

A somewhat different picture is presented in the pulverized-fuel column. In only one pressure class does the fuel-burning equipment, i.e., the burners and pulverizing and conveying equipment, take a position as one of the three largest sources of outage. In the 300–399-lb class considerable time was spent in replacing mill hammers, liners, and grinding balls, but in all other instances the operators considered such outages as normal.

TABLE 9 MAJOR OUTAGES

Pressure class	Stoker-fired units			Pulverized-fuel-fired units			Oil- and gas-fired units		
	Order of magnitude	Part of unit crippled	Reason for outage	Order of magnitude	Part of unit crippled	Reason for outage	Order of magnitude	Part of unit crippled	Reason for outage
500–700 lb...	1	Furnace	(a) Plain refractory walls	1	Furnace	(a) Arch failures			
			(b) Low fusion coal			(b) Burned secondary-air-inlet parts			
	2	Stoker	(a) Burned parts due to preheated air	2	Economiser	(a) Some tubes rerolled twice each month			
			(b) Mechanical drive						
	3	Boiler and superheater	(a) Overloaded soot blowers due to coal used						
			(b) Replacement of tubes						
400–499 lb...	1	Stoker	(a) Burned parts due to preheated air	1	Boiler and superheater	(a) Rearrangement of superheater supports			
			(b) High ratings			(b) Failure of superheater tubes			
			(c) Removal of secondary rams and links on link grates						
	2	Boiler and superheater	(a) Renewal of valve seats and disks	2	Furnace	(a) Rearrangement of front walls to secure more suitable air distribution			
	3	Cleaning gas side of heating surface	(a) Plugged air preheaters						
			(b) Excess slag accumulation						
300–399 lb...	1	Stoker	(a) Burned stoker parts	1	Furnace	(a) Failure of water-cooled steel blocks	1	Boiler and superheater	(a) Warping of support members by leaking gases
			(b) Mechanical drive			(b) Rebuilding refractory walls			(b) Leaking stop valves
	2	Boiler and superheater	(a) Tube replacement	2	Boiler and superheater	(a) Replacement of radiant-superheater elements	2	Furnace	(a) Chipping of burner wall brick
			(b) Valve repair			(b) Superheater tubes cut by steam from misaligned soot blower			
			(c) Failure of radiant superheater elements						
			(d) Slag deposits						
	3	Furnace	(a) Slag deposits	3	Pulverising equipment	(a) Renewal of mill hammers, liners, grinding balls			
			(b) Rebuilding refractory walls	4	Draft equipment	(a) Vibration of induced-draft fans			
						(b) Erosion of fan blades by fly ash			
						(c) Failure of fan-shaft assemblies at preheaters			
200–299 lb...	1	Boiler and superheater	(a) Replacement of tubes	1	Boiler and superheater	(a) Tubes cut by steam from misaligned soot blowers			
						(b) Overheated superheater tubes			
	2	Furnace	(a) Rebuilding refractory walls						
	3	Stoker	(a) Burned parts due to low-ash, low-volatile coal						
			(b) Mechanical drive						

Furnace troubles were much the same as with the stoker-fired units where plain refractory walls were concerned. In the cooled or protected walls considerable outage was due to the burning of the wall surface. In the case of one station the bare steel blocks were removed after unsuccessful attempts to keep them in service, and cast-iron blocks were substituted for them. The results had been satisfactory at the time of the last report. In another instance the bare secondary air-port blocks burned badly, necessitating frequent replacement.

Two stations experienced difficulty in maintaining correct alignment of soot-blower elements due to warping. The result was the cutting of boiler and superheater tubes to such an extent that tube replacements were abnormal.

Only one station reported outages other than normal in the oil-and-gas-fired group. Even these were of a comparatively minor character, and all repairs were made during scheduled overhaul periods.

Conclusions

In general, the results of the three-year study bear out the relationships indicated by the 1929 report, the differences being only those of degree. All groups and classes have apparently dropped slightly in availability, probably because of added outages, which generally are not annual occurrences. The question of age might arise, as the greater number of units included in the study were two years older at the end of the three-year period than they were in 1929, but it is not believed to have had much influence in this case because of the fact that boilers of radically different ages were considered in both the short-time and long-time studies.

There still seems to be no appreciable difference in reliability between pulverized-fuel firing and stoker firing. The small margin in favor of the former method is very small when compared with the range between high and low individual values in both groups. While it is true that outages due to the stoker proper are somewhat greater than those chargeable to the pulverizing and burning equipment alone, it must be kept in mind that there are many other factors of intangible character which might easily have a more than balancing effect. Such factors are the amount of stoker and pulverizer repair work done as scheduled overhaul, and local fuel and load-schedule conditions. Also, as pointed out in both previous papers, any hard and fast conclusions must be avoided in a study of this kind because of the many variables involved and the differences of opinion and maintenance standards which are inevitable in a widely scattered group of some sixty-odd operators.

Probably one of the most illuminating parts of this final study is the material contained in Table 9. The influence of local conditions is brought out very sharply. Many units are afflicted with a very poor grade of coal, while others suffer from the use of fuel of too high a grade. Experiments in design are being conducted in many stations. Preheated air is becoming more generally understood.

The modern steam-generating unit seems to have been in a state of rapid and constant development at the time when these data were collected. The authors have reason to believe that this is still the case. Such development inevitably results in abnormal operating and maintenance conditions, which are reflected in the data collected. Suffice it to say that even in this transitory stage, modern steam-generating equipment may be relied on for use from 82 to 86 per cent of the time. There is every indication that this state of affairs will improve somewhat in the future, but until changes in design have become less radical and operating methods more standardized, many abnormal conditions will arise which will tend to confuse and distort the impressions of the investigator and append the question mark to many of his conclusions. For this reason the authors are terminating their study with this paper, believing that a continuation at this time would not be productive of any appreciable increase in the knowledge of the art.

Influence of Bends in Inlet Ducts on the Performance of Induced-Draft Fans

By L. S. MARKS,[1] J. LOMAX,[2] AND R. ASHTON,[3] CAMBRIDGE, MASS.

This paper shows the great loss in capacity and efficiency of a fan that results from the location of elbows or bends close to the inlet boxes. The loss is shown to be a function of the type of bend, of its "aspect ratio" or ratio of depth to width, and of the direction in which the air is turned in the bend. By the use of guide vanes in the bend the loss can be almost entirely prevented. When scroll inlet boxes provided with guide vanes are used, this loss does not occur, but the capacity with such boxes is low, although the efficiency is maintained. The cause of the loss is not the friction in the bend, but is the poor distribution of the air leaving the bend and entering the inlet box. The use of a short length of straight duct between the bend and the inlet box will reduce the loss appreciably. Measurements by pitot tube of the distribution of velocity and static pressures at the entrance to the inlet boxes will indicate the existence of this loss and the desirability of inserting guide vanes in the bends.

L. S. MARKS

JOHN LOMAX

RANDOLPH ASHTON

IN A paper by one of the present authors (and another), before the Society in 1931,[4] the results were presented of tests on the influence of the inlet box on the performance of induced-draft fans. It was stated in that paper that the direction and velocity of approach of the gases at the fan inlet were determined by the form and dimensions (1) of the inlet box and (2) of the ducts leading the gases to the inlet box. In the present paper, the second of these factors is considered.

In the great majority of installations, the induced-draft fan is located high up in the power plant. The ducts conveying the gases come from below and make a sharp bend close to the inlet boxes of the fan. The investigations here presented had for their purpose (1) the determination of the influence of such bends on the fan performance and (2) the investigation of means to counteract the harmful effects of such bends. It is found that certain bends diminish greatly the capacity of a fan, but that this capacity can be in large part restored by simple and inexpensive means. It also is demonstrated that the pressure drop in the bend has only a minor influence on fan performance and that the important factor is the lack of uniform distribution of the gases leaving the bend.

The tests were carried out at the Gordon McKay Laboratory of the Harvard Engineering School. The fan used was a double-inlet, Turbovane, induced-draft fan supplied by the B. F. Sturtevant Company. This is the same fan that was used in the tests reported last year. The wheel, Fig. 1, is double-inlet, 38 in. diameter, $23^5/_8$ in. wide, and has radial tips. It is provided with curved aluminum inlet rings. In the majority of tests the modified rectangular box shown in Fig. 2 was used. This is the box that was found to give a performance practically identical with the performance with free inlet. In a few tests a scroll inlet box with guide vanes, Fig. 3, was substituted. This is the box that was found to reduce the capacity of the fan about 30 per cent below the capacity when using the box of Fig. 2. It was used in these tests with the expectation that the vanes would redistribute the arriving gases in such a way as to offset the disturbing effect of the bends; this expectation was in large part realized.

Nearly all the tests were made with the bends bolted directly to the inlet boxes and with a short length of straight duct, with flared inlet, preceding the bend so as to provide uniform air flow to the bend. In some supplementary tests short lengths of straight duct were inserted between the bends and the inlet boxes, to ascertain the extent to which a uniform flow could be reestablished by this means before the air reached the inlet boxes.

Three types of bend were used, long-sweep 45-deg and 90-deg elbows and square elbows. The details of these bends for the modified rectangular box are shown in Fig. 4 and for the scroll inlet box in Fig. 5. It will be seen that the depth of the duct in

the plane of the bend is much greater than its dimension at right angles to that plane. For the modified rectangular inlet box this "aspect ratio" is 55 to 17 and for the scroll inlet box it is 31¾ to 18. These high ratios are presumably unfavorable to a good velocity distribution past the bend, and the tests indicate that inlet boxes with smaller aspect ratios would not show so great a loss of capacity resulting from the use of bends close to the inlet boxes.

Each bend was tested in two positions—(1) so oriented as to cause general flow of the air through the bend with the same direction of rotation as the rotation of the fan wheel and (2) with the bend turned through 180 deg so as to reverse this general direction of flow.

The arrangement for the tests is indicated in Fig. 6, which shows a modified rectangular inlet box, a 90-deg long-sweep bend in the position apparently giving air rotation opposed to the direction of rotation of the fan wheel, and a short straight duct with flared inlet. The tests were made in accordance with the Standard Test Code with the exception, necessitated by the objects of the test, that bends were substituted for the prescribed straight inlet ducts. The inlet total pressure was taken as atmospheric pressure except for the "corrected" results. These "corrected" results assume that the total inlet pressure at the fan is equal to the atmospheric pressure minus the friction loss

in the bends. The friction losses in the bends were calculated by using the results of the investigations of Loring Wirt[5] and, as already indicated, were found to be comparatively unimportant.

Power input was determined by both electrical and mechanical measurements. The agreement was very close; the mechanical measurements were used in calculating the fan performance.

[5] *Genl. Elec. Rev.*, June, 1927, pp. 286–296.

All tests were made at a speed of about 800 rpm and were corrected to 900 rpm and an air density of 0.07488 lb per cu ft.

The results of the tests with the modified rectangular inlet boxes are given in Table 1, which includes also, for comparison, a test with a short straight duct and no bend. The influence of the bends on the performance of the fan is shown in Figs. 7 to 10. The numerical comparison of Table 2 gives fan capacities at

5 in. static pressure, which is about the desirable normal operating condition for this fan at 900 rpm. It is seen that the loss in capacity for 90-deg bends is approximately twice the loss with 45-deg bends and that the loss in square bends is very great, being in one case almost twice that of a 90-deg long-sweep bend. It also is noteworthy that the capacity is greater when the direction of air rotation in the bend is opposed to the direction of rotation of the wheel. If the air were actually rotating as it entered the fan wheel, this result would seem anomalous, but there is no reason to expect that any definite spin would result

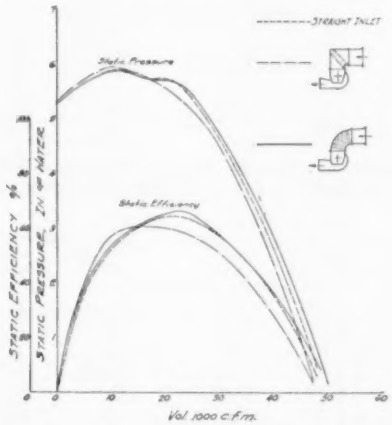

FIG. 21 LONG-SWEEP AND SQUARE BENDS WITH GUIDE VANES, OPPOSED ROTATION

(Air rotation through the bend in the same direction as the rotation of the fan wheel.)

from the passage of the air around the bend. The actual effect of such passage is rather a crowding of the air on the outer side of the bend. This is shown by pitot-tube readings, as indicated later.

The influence of the bends on fan efficiency also is shown in Figs. 7 to 10. It is interesting to note that with air rotation opposed to wheel rotation (which gives higher capacity) the efficiency is considerably lower. The maximum static efficiency falls from 64 per cent with a straight duct to 55 per cent with 45-deg and 90-deg bends and to 52 per cent with a square bend.

USE OF GUIDE VANES IN BENDS

The tests described indicate clearly that the ill effects of bends are due to the resulting poor distribution of the air arriving at the fan inlet. It seemed that this distribution could be improved by the use of guide vanes in the bends, which would have the effect of converting a single bend into a number of concentric bends of low aspect ratio. The details of the guide vanes used

are shown in Fig. 11. In the case of the square bends, the diagonally located guides are of circular form, all of the same radius.

The results of fan tests using these guide vanes in the bends are given in Table 3 and are shown in Figs. 12 to 21. It is apparent on inspection of Figs. 12 to 17 that the full capacity of the fan can be in large part restored by the use of such guide vanes in long-sweep bends. Moreover, it appears from Figs. 14 and 15 that three guide vanes, or an aspect ratio of about 0.8, give almost as good a fan performance as seven guides, or an

aspect ratio of about 0.4. A smaller number was not tried, but it would appear probable that the harmful effects of long-sweep bends next to the inlet boxes would not be serious so long as the aspect ratio of the duct is not greater than unity.

The guide vanes used with the square bends restore nearly the full capacity with opposed direction of air flow but with some loss in efficiency (Fig. 19), and with the same direction of air flow give it full efficiency but with some loss in capacity (Fig. 18). The gain is greater than with the long-sweep bends, but the fan performance is definitely inferior to that with long-sweep bends and guide vanes. This is clearly shown in Figs. 20 and 21.

STRAIGHTENING THE AIR FLOW PAST THE BENDS

In many installations it is possible to insert short lengths

of straight duct between the bends and the inlet boxes. It is a commonly accepted belief that a straight duct whose length is from three to four times the mean of the width and depth of a rectangular duct will result in the restoration of fairly uniform air distribution in the duct. In order to find the effect on fan performance of the introduction of a short length of straight duct, the 90-deg long-sweep bend was used in a position to give air rotation in the bend in the same direction as the rotation of the wheel. This arrangement is shown in Fig. 22. The lengths of duct used were 5 ft 5 in. and 10 ft 5 in., corresponding respectively to 1.8 and 3.5 times the mean duct dimension.

The results of these tests are given in Table 4 and in Fig. 23. It is seen that the shorter length of duct is practically as effective as the greater length and that in both cases nearly half of the loss in capacity is restored and the loss of efficiency is in large part regained. As the ducts introduce friction loss which in Table 4 and Fig. 23 is charged against the fan, further calculations have been made correcting the static pressure for the friction loss in the bends and in the ducts. The results of these are shown in Fig. 24, which indicates that the ducts restore more than half the loss in capacity and that the full fan efficiency is regained.

It may be noticed in Figs. 23 and 24 that the tests with short straight ducts inserted were made with a horizontal position of the inlet boxes. They were compared with tests (1) without a bend and (2) with a bend next to the inlet box, and in both cases with a vertical position of the inlet boxes. That this change, necessitated by the vertical height of the laboratory, has no influence is indicated by the good agreement between the test without bend here reported and the similar test reported last December,[6] which was made with horizontal inlet boxes.

Scroll Inlet Boxes

A series of tests was made with scroll inlet boxes and vanes, as shown in Figs. 3 and 25, to ascertain whether a fan with this type of inlet box was sensitive to non-uniformity of the air stream approaching the inlet or whether the vanes at the inlet made the fan comparatively "foolproof" in the matter of inlet-duct arrangement. The fan was tested with a short straight inlet duct and with 45-deg and 90-deg long-sweep bends of the dimensions shown in Fig. 5. The tests included both orientations of each bend, so as to ascertain the influence of air-rotation direction. The results of these tests are given in Table 5 and Figs. 26 and 27.

An inspection of Figs. 26 and 27 shows that the bends have a negligible influence on the fan performance. Under the conditions of Fig. 27, no effect can be detected when a 90-deg bend is added; and consequently, since the results given are uncorrected for elbow friction, the actual performance of the fan itself was improved. With the 45-deg bend this is still more marked, both as to capacity and efficiency. Under the conditions of Fig. 26, an inferior performance is seen for the 90-deg bend, while with the 45-deg bend the performance is inferior at high capacities and superior at medium capacities. The fan is seen to be practically unaffected by the inlet-duct conditions.

This advantage of the scroll inlet box is obtained at the cost of a considerable reduction in capacity but with a marked increase in maximum efficiency when the air rotation in the bend is opposed to the direction of rotation of the wheel. This is seen in Figs. 29 and 31, which compare the two types of inlet box with 45-deg and 90-deg bends, respectively. With the reversed position of the bends, Figs. 28 and 30, the maximum efficiencies are unchanged, but the capacity does not fall off so much.

Direction of Air-Stream Rotation in the Bends

It is not suggested in this paper that the air in passing through a bend is set in rotation. The term rotation is used merely to indicate the direction in which the stream of air entering a bend is deviated from a rectilinear path. If this direction, as viewed from the side of the fan, is the same as the direction of rotation of the fan wheel, the air flow is spoken of as being in the same direction of rotation as the wheel.

The air-flow direction in the bends has a considerable influence on fan performance in those cases where the influence of the bend is considerable. For bends provided with guide vanes or with the scroll inlet box, this influence is small, but is recognizably of the same kind. With opposed air flow, the capacity (cfm at a given static pressure) is greater than with the same direction of flow, with the occasional exception of a reversed condition at low capacities. This is shown clearly in Figs. 32, 33, and 34. At

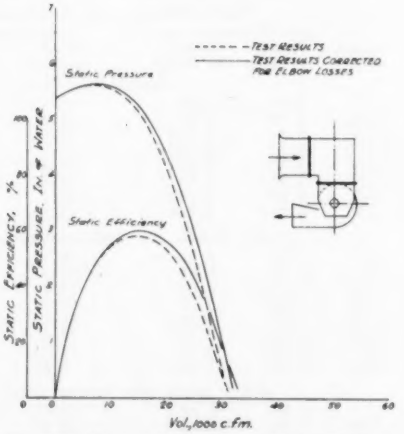

FIG. 36 ELBOW-LOSS CORRECTION, SQUARE BENDS

the same time the efficiencies with opposed air flow are less than with the same direction of flow, except at the highest capacities (cfm). At the normal operating range the difference in capacities is not great, but the difference in efficiencies is considerable. Consequently, the preferred condition for a normal installation should be with air rotation in the same direction as wheel rotation.

CORRECTION FOR FRICTION LOSS IN THE BENDS

The test results and the comparisons already given, with the exceptions specifically noted, consider the bends as part of the fan and neglect the friction losses up to the inlet boxes. The total pressure at the inlet boxes is assumed to be atmospheric pressure. It is obvious that this assumption reduces the static pressure and the static efficiency of the fan below the true values and makes the comparison between a fan with bends and a fan without bends less favorable than it should be. The influence of the bends consequently appears to be greater than it actually is.

Corrections for friction losses can be made if these losses are known with sufficient accuracy. The investigations of Wirt[7] appear to be the only ones available that can be directly applied to this case. Although those investigations seem to be of a high order of accuracy, the authors have thought it best not to rely on them in the presentation of their experimental results.

Calculations have been made on the basis of Wirt's work, and they show that the friction loss is a minor factor when considered in relation to these tests. The corrections attain a maximum value for the tests shown in Figs. 35 and 36, and these are for conditions for which the influence of the bends on air distribution is a maximum, so that the friction effect is comparatively unimportant. In general, since these tests are made on a particular fan provided with particular bends, the exact magnitude of the results obtained are not important. Ignoring the small friction loss does not affect the general results.

DETECTION OF POOR AIR DISTRIBUTION AT THE INLET BOXES

Pitot-tube readings were taken at three locations (see Fig. 6) at the entrance to the inlet boxes during most of these tests. As the air flow is highly irregular at this location when bends are used and as the direction of flow is presumably not parallel to the axis of the duct, it is obvious that pitot tubes oriented parallel to that axis cannot give correct impact or static pressures. It was found, however, that they gave important indications as to uniformity of flow. In the case of the bends without guide vanes, the velocity head was high on the outer side of the bend, while the static pressure was high on the inner side of the bend. It is thought that the conditions of air distribution in any installation can be simply determined by a pitot-tube search of this kind. The evidence available is not considerable, but indicates that with good air distribution a pitot tube located as suggested will show practically constant velocity head in all positions and will show static pressure a little higher in the

[7] *Loc. cit.*

middle of the duct, but without much change in going to the outer positions along the depth of the duct.

Acknowledgments are made to the B. F. Sturtevant Company for the loan of the fan and for supplying the ducts used in this investigation.

Discussion

H. F. Hagen.[8] The reductions in output reported by the authors explain satisfactorily the unsuccessful fan performances encountered so frequently in induced-draft work. Many power plants have curving inlet flues that give the kinds of flows investigated by the authors. The bad effect of such conditions has been understood, at least partially, for some time. It was to avoid these trouble jobs that the writer undertook to develop a fan with a stable performance that would be unaffected by poorly designed flue work.

Experimentation discouraged the use of vanes placed directly in a conventional inlet box. The uneven distribution of air flow apparently occurred before the air entered the box, and no effective arrangement of vanes was discovered that would correct what was already wrong.

The spiral box with vanes was then worked out, and it accomplished the main purpose of the research. The design had the disadvantage of requiring a somewhat larger and more expensive fan when test-block performances alone were considered. Actually, as may be seen by a comparison of the stable curves of the scroll-inlet fan, Figs. 26 and 27, with the reduced, or what might be called the "installed," performances of the simple box, Figs. 7, 8, 9, and 10, the scroll-inlet capacity is fully as great as the capacity of the simple box under actual installation conditions. Its efficiency is much higher, and there is no unexpected, and consequently disastrous, drop in performance. In fact, if tests of the simple box had been made with flues installed, as the authors have done in their tests, there would have been no question about the advantages of the scroll-inlet fan from all standpoints.

Professor Marks' ingenious use of directing vanes in the elbows before the boxes has shown that it is possible to get stable performance with simple boxes with suitable flow conditions, and he has secured the highly desirable results of stable performance and maintained efficiency with no sacrifice of capacity. His work is important to the power-plant operator in showing how large improvements can be made inexpensively in existing installations. The work is also of vital interest to the fan manufacturer as a suggestion for future development.

However, it is almost a necessity that the vanes as used in Professor Marks' experiments be made part of the flue work, and there may be some hesitation on the part of purchasers to assume the consequent responsibility of correcting the flow of gases before the fan even though the fan engineers may be willing to share this responsibility.

The scroll-inlet fan has come through the tests showing that it could as a self-contained unit compensate fairly completely for almost any condition of flow. The installation of a fan designed after this manner would permit the fan manufacturer to assume a clear-cut responsibility, and possibly at a somewhat decreased hazard.

As a result of the authors' work we can feel reasonably certain of successful performance with either the simple box and suitable vanes in the connecting flues or with the self-contained scroll design. The simple box at present is less expensive, while the scroll design may be somewhat more generally reliable. The writer has a leaning toward the fan that is stable in itself and does not depend upon necessary corrective design on the part of others who may not be entirely familiar with the principles involved. Both types of fans are being used at the present time and it will be interesting to observe future tendencies.

C. E. Peck.[9] The data in this paper show the importance of obtaining uniform air distribution at the entrance to a fan. Non-uniform distribution is the principal reason why fan performance in the installation differs considerably from that obtained under test conditions where the inlet is free or special precautions are taken to insure uniform air distribution. Other duct constructions, in addition to bends, which may be located close to the fan inlet and which affect distribution considerably are:

1 Ducts with large total angles of divergence near blower inlet
2 Dampers or regulating valves
3 Sudden change in duct cross-section from a smaller to a larger area.

It has been the writer's experience that a round diverging duct with a total conical angle of divergence as small as 20 deg will not only tend to reduce the fan capacity, but also to produce

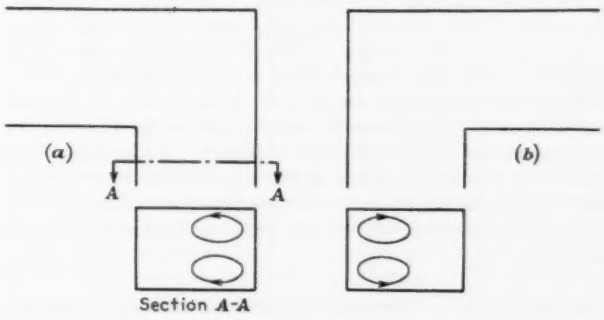

Fig. 37

cyclic variations in the capacity and power input of considerable magnitude. A rectangular duct which diverged in one direction only with an angle of approximately 20 deg caused very unstable fan operation when placed near the inlet of a propeller-type blower. Irregular cyclic variations in capacity of 50 to 75 per cent took place, accompanied by increased noise. This unstable condition existed over the entire pressure-volume range. It was observed in this particular case that the air stream did not follow both sides of the diverging wall simultaneously, but only one side or the other, an irregular shifting of the stream suddenly taking place. Simultaneous with the shifting of the air stream in the diverging duct, the large variations in fan capacity would take place. Various combinations of baffling and screening did not reduce the intensity of this unstable condition to any marked degree. The obvious remedy of reducing the angle of divergence to a small amount (4 to 6 deg total angle), by lengthening out the duct, eliminated this unstable condition.

The foregoing emphasizes the need of carefully laying out the duct installation in which a fan must operate if efficiencies near to those obtained under standard test code conditions are to be maintained. Also, any type of duct construction which may produce non-uniform air distribution at the blower inlet tends to increase the windage noises. In some cases, depending on the type of inlet to the fan, non-uniform air distribution causes marked increases in amount of noise.

[9] Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Jun. A.S.M.E.

With regard to the flow in the bend, the results indicated that the blower performance was changed depending on the position of the bend relative to the rotation of the blower. As shown in Fig. 37, the flow after the turn has been made gives rise to the well-known "secondary flow," which consists of localized rotations in a plane approximately perpendicular to the side walls of the duct. In (*a*), the direction of the secondary whirls are opposite to those in (*b*), looking at a cross-section of the exit side of the turn. This difference in direction of the flow in each case for the same direction of the rotation of the fan is probably linked up with the difference in blower performance.

The magnitude of these secondary whirls determines the "piling up effect" on the outer wall of the bend, which in turn influences the air distribution in the duct beyond the bend. This depends on the shape of duct, radius ratio at the turn, aspect ratio, etc. The influence of these factors on the losses in elbows has been quite thoroughly investigated by Loring Wirt. (See footnote 5 of the paper.) The authors have shown comparisons of effects on performance with a fixed aspect ratio. For the modified rectangular inlet box, this aspect ratio is defined as 55 to 17. If used in the same sense as in Wirt's article, the aspect ratio is defined in the inverse manner—namely, 17 to 55. Used in this way, Wirt gives data which show that the loss in the elbow increases with decreasing aspect ratio. Similarly, the authors' tests indicate that inlet boxes with larger aspect ratios would not show so great a loss of fan capacity when bends are close to the inlet boxes. This, together with Wirt's tests, indicate that the greater the loss in the bend, the greater the non-uniformity of distribution and the greater the effect on the fan performance when the bend is close to the blower. This conclusion is useful, because if the loss in the elbow is kept small, it may be placed in the duct system close to the fan with little sacrifice of capacity, and the use of guiding vanes may be eliminated.

W. R. Heath.[10] This paper should be of interest to all users of induced-draft fans and to all designers of mechanical draft systems, as it gives the results of carefully made tests showing the influence of various types of bends on the performance of one type and one design of induced-draft fan. Whether the same bends would have the same influence on another type or design of fan is open to question. The writer has observed tests made under unfavorable inlet conditions which show very plainly that a fan with open inlet is much more sensitive to variations of flow approaching the inlets than is a fan fitted with properly designed fixed inlet vanes. The latter fan was very definitely a more "foolproof" type, and in addition the use of vanes at this point improves to a marked degree the fan efficiency.

The influence of the various bends on capacity is interesting, but the efficiency is not of much moment, since the particular type of fan under test does not have the desirable non-overloading horsepower characteristic, and it would be necessary in most applications to provide reserve motor capacity anyway on this account.

The comparison of capacities in Table 2 are based on a constant pressure, which is misleading from a practical application viewpoint. For instance, if a fan were selected to give 27,500 cfm and 5 in. static pressure at 900 rpm, which is the operating condition selected by the authors, the user would desire to know the expected decrease in capacity when operating on the same system and at the same speed and with the type of bend used. Of course, if the capacity were decreased, the resistance of the system would no longer be 5 in., but would become a less value determined by varying this pressure as the square of the capacity. In other words, the "system characteristic" should be plotted and the capacity interception of this curve with the pressure curve of the fan when throttled by the individual bend should be compared with the original 27,500 cfm desired. Incidentally, this is the method of comparison used in the A.S.M.E. paper of 1931 by one of the co-authors of the current paper.[11] On this basis, Table 2 would show:

		—System-characteristic—method		—Constant-pressure—method	
Type of bend	Direction of rotation	Capacity	Actual decrease in capacity, per cent, compared with straight duct	Capacity	Decrease in capacity, per cent, shown in paper
Straight duct	.....	27,500	...	27,500	...
45-deg bend	Same	24,800	10.0	23,800	13.5
45-deg bend	Opposed	26,100	5.0	24,900	9.5
90-deg bend	Same	24,750	9.5	19,500	29.0
90-deg bend	Opposed	26,100	4.75	22,000	20.0
90-deg square	Same	22,300	18.5	15,900	42.0
90-deg square	Opposed	23,700	13.5	16,900	39.0

The new table shows that, when compared on a practical basis, the decrease in capacity of the particular fan under test with the various type of bends averages one-third to one-half the values indicated by the paper—still too much to ignore, but considerably less than the authors intimate.

Under the heading, "Straightening the Air Flow Past the Bends," and in Fig. 24, the authors show that by introducing a straight length of duct 5 ft. 5 in. long (1.8 diam) the loss in capacity is restored by more than half. However, the addition of another 5 ft 0 in. (1.7 diam) restores a very small portion of the balance of the loss. It is therefore reasonable to suppose that each additional 5 ft 0 in. of duct will have less and less effect, or, in other words, that it would be impossibie to restore the full fan capacity by any practical length of duct. It would then follow that a bend anywhere in the system would have a harmful effect on the performance of this particular fan. This would indicate one of two things: (1) that the base curve of the fan with straight boxes is higher than could be duplicated on future tests and therefore in error, or (2) that the particular fan under test was unduly sensitive to slight changes in air flow. The latter is more likely, since the fan inlet is open (i.e., not equipped with guide vanes to stabilize its performance). Furthermore, the "wave" in the pressure curve so apparent in nearly all the curves strongly indicates an unstable condition inherent in the fan at at least one point; also, this is the same fan which was used in preparing the paper a year ago, previously referred to, in which the authors found that with rectangular boxes without guide sheets, "the performance was unstable" and that "the fan would develop periodically a roaring noise which coincided with a power increase of 10 to 15 per cent, but without noteworthy change in the discharge volume."

This paper claims certain advantages for the scroll-type inlet boxes when there are bends at the entrance to the boxes. An investigation of the data, however, shows the following:

Assume the same desired condition of 27,500 cfm and 5 in. static pressure at 900 rpm with a 90-deg bend at entrance to the boxes and with the preferred condition of air rotation the same as wheel rotation. Selecting the proper size fan both with rectangular-inlet boxes and with scroll-inlet boxes from the data corresponding to Fig. 10 and Fig. 26, respectively, thus taking full account of the effect of the bend on the fan performance, gives the comparison shown on the next page.

Hence, it is apparent that, as concluded in the 1931 paper, the scroll-inlet boxes fall below the rectangular-inlet boxes in

[10] Assistant Chief Engineer, Buffalo Forge Company, Buffalo, N. Y.

[11] "Influence of Inlet Boxes on the Performance of Induced-Draft Fans," by L. S. Marks and E. A. Winzenburger, Trans. A.S.M.E., vol. 54, no. 21 (1932), paper FSP-54-16.

Type box	Size fan	Cfm	Static pressure, in.	Rpm	Hp
Scroll.....	41½	27,500	5	900	40.3
Rectangular...	40¼	27,500	5	900	37.4

NOTE: Points on curves for fan performance from which these ratings were selected are from actual readings as given in the paper.

the order of merit. In the foregoing example, the fan with rectangular boxes would be slightly smaller, and therefore slightly cheaper, would have a less expensive construction of inlet boxes, and would consume less power. In addition, when the induced-draft fan handles gas with a considerable concentration of fly ash, as is so frequently the case, the scroll-inlet boxes would be subject to a scrubbing action by the ash and consequent erosion in a manner similar to the fan housing scroll itself without relieving the wear on the rest of the fan. This condition is not present with rectangular boxes.

The following is a summation of the foregoing discussion: (1) The paper shows completely the influence of bends in inlet ducts on the performance of one type or design of induced-draft fan only—a type of fan that does not have the desirable nonoverloading horsepower characteristic and a type of fan that shows some inclination toward inherent instability. The findings are not applicable to a fan fitted with properly designed fixed-inlet vanes. (2) The comparisons given in Table 2 are not made on a practical basis. (3) Rectangular boxes are, when intelligently used, a better selection than scroll-type boxes.

W. A. ROWE.[12] Under the heading, "Direction of Air-Stream Rotation," there is indicated the basis for the designation. If one will refer to Fig. 25, showing the arrangement with scroll inlet, it would seem as though a more appropriate designation with the scroll-inlet box would have reference to the side of the center line on which the downcomer is connected to the duct. As long as the inlet duct is connected to the right-hand side of that elevation, the direction the air takes with reference to the wheel might be more properly designated as of the same rotation. This would then be true were the 45-deg bend tilted in the opposite direction as well.

The consistency in the performance when viewed in this manner is indicated by the curves in Fig. 27 and the heavy-line curves on Figs. 28, 29, and 30. This interpretation would lay emphasis rather on the direction that the air particle takes in the inlet box just prior to entering the inlet of the fan and with reference to the direction of rotation of the fan wheel, rather than on any changes in direction at more remote locations in the inlet ducts.

It might be pointed out that while these determinations were based on one particular type of fan, there are other types of fans of equal or even possibly wider use in induced-draft work. In the case of all these types not only is care in the design of the inlet boxes and connections important, but it is also necessary to avoid unfavorable outlet connections. Failure to observe these precautions constitutes the great majority of fan-trouble jobs or complaints.

[12] American Blower Corporation, Detroit, Mich.

The important part of this contribution is to my mind disclosed in the last paragraph on the fifth page, where it is pointed out that the full capacity of the fan can be in large part restored by the use of proper precautionary measures in the design of the bends. Many years' experience in the adaptation of apparatus to commercial applications convinces that there are an almost infinite number of combinations of poor arrangements that can be encountered. The wide distribution which information of this kind will receive it is hoped may correct in large measure mistakes in the future by those who design or install those parts of the systems. While the fan manufacturer should for his own interest be on the alert to anticipate possible problems of this kind in order to prevent them at the inception, he should not be held to a guaranty of performance so all-embracing as to include every possible external disturbance of this nature.

This paper confirms the propriety of the existing Fan Testing Code in its refusal to approve any approximate method of field testing which might be used for the purpose of determining whether a fan complies with or fails to comply with its guaranteed performance. The code does not say where the test shall be made, but how it is to be done, and such check tests may be made either in the laboratory or the field, providing the method and means used comply with the provisions of the test code.

AUTHORS' CLOSURE

The authors are glad to have the confirming statements by Mr. Peck and to have his list of additional causes of lack of uniform air flow. The quantity called the "aspect ratio" in this paper is the reciprocal of the quantity so called in Wirt's paper.

With reference to the discussion by Mr. Heath, the authors believe that since the loss of capacity is due to poor distribution of the air approaching the fan inlet, the loss is likely to be of the same order of magnitude for all fans which are not provided with devices for overcoming this poor distribution. The authors are glad to have Mr. Heath's additional table showing the influence of bends on the capacity of a fan connected with a given system. This table is perhaps the most generally useful comparison. Table 2 was prepared as giving the basis for determining the increase in size of fan necessary for maintaining the fan capacity with the stated resistance and tip speed.

No evidence is presented by Mr. Heath to support his conclusion that the findings of this paper are not applicable to a fan with fixed inlet vanes. The second paragraph in Mr. Hagen's discussion of this paper presents a contrary view to that suggested by Mr. Heath. The authors have no first-hand information on this subject. In any case, it would appear to be preferable to obtain a uniform air stream entering the inlet boxes rather than attempt to correct lack of uniformity by special devices at the fan.

In reply to Mr. Rowe, the "direction of air-stream rotation" is defined as the direction in the bend, and this was the variable in the tests. A reference to Table 5 and to Figs. 26 and 27 shows that the performance of the fan with scroll-inlet boxes is affected by this direction of air-stream rotation, though not to as great an extent as with simple inlet boxes.

FSP-55-10

A System for the Measurement of Steam With Flow Nozzles for Turbine Performance Tests

By SANFORD A. MOSS[1] and WISTAR W. JOHNSON,[2] LYNN, MASS.

S. A. Moss

In this paper the authors give particulars regarding a system of steam-flow measurement by means of a nozzle for performance tests of jet-condensing, non-condensing, or extraction turbines where condensate measurements are out of the question. The system as outlined is on a laboratory basis in order to insure the accuracy necessary when steam-turbine guarantees are involved. One of the two appendixes presents an account of tests on which the system is based; the other deals with formulas for steam flow.

W. W. Johnson

THIS paper presents a system of steam-flow measurement by means of a nozzle for performance tests of jet-condensing, non-condensing, or extraction turbines where condensate measurements are out of the question. The flow is calculated from the pressure and temperature ahead of the nozzle, the direct reading of the differential pressure across the nozzle, and the dimensions of the nozzle and pipe. The system as outlined is on a laboratory basis in order to insure the accuracy necessary when steam-turbine guarantees are involved. Appendix No. 1 includes an account of tests on which the system is based.

This system was initiated by E. D. Dickinson, designing engineer of the Steam Turbine Department at the Lynn Works of the General Electric Company. It is based on recognized principles for the measurement of air at ordinary pressures,[3] of high-pressure air,[4] of low-pressure air from blowers,[5] and as an actual standard for calibration of orifices in thin plates.[6] Reference is made also to work at the Engineering Experiment Station at Ohio State University by Profs. S. R. Beitler and Paul Bucher.[7]

The Flow Nozzle

The Nozzle Shape, shown in Fig. 1, shall include a well-rounded approach formed by two circles which practically give a quarter-ellipse with a ratio of axes of 3:2. This is very nearly the shape used by the Bureau of Standards in Research Paper 49 already cited.

Nozzle Throat. However, even though there is a very gradual approach, it cannot be certain that the jet will completely fill the curved portion of the nozzle. Therefore, at the end of the curved portion, there shall be a parallel portion forming the nozzle throat, with a length of at least half a nozzle diameter. This is to insure that the jet has the exact diameter of the nozzle parallel portion at the point where its static pressure is taken and leaves no uncertainty as to jet size to be taken account of by the nozzle discharge coefficient.

The Throat Diameter D shall be selected to give differential pressures of at least 2 in. of mercury for the smallest flow and between 10 in. of mercury and 10 per cent of the high-side pressure for the largest flow with usual steam pressures. It is not proper to use a differential pressure too small for accuracy, to avoid pressure loss. It is obvious that the greater the differen-

[1] In charge of Mechanical Engineering Research, Thomson Research Laboratory, General Electric Co. Mem. A.S.M.E. Dr. Moss began his engineering career by serving a four years' apprenticeship as a machinist in San Francisco, Calif., afterward spending some years as a draftsman. He entered the University of California and was graduated from the College of Engineering in 1896, afterward receiving a Master's Degree from the University of California and a Doctor's Degree from Cornell University. This college work was interspersed with professional work as a draftsman and engineer. He became associated with the General Electric Company in 1903 and has since been engaged on mechanical engineering research work connected with gas turbines, steam turbines, centrifugal compressors, and superchargers for internal-combustion engines. He has been granted a number of patents for apparatus produced by the General Electric Company.

[2] Turbine Department, General Electric Co. Mem. A.S.M.E. Mr. Johnson received the degree of A.B. from the University of Oregon in 1907, B.A. from Oxford University in 1911, and B.S. from Massachusetts Institute of Technology in 1913. He has been associated with the General Electric Co. since 1913, with the exception of 1920, when he was connected with the Federal Shipbuilding Co. His work has been in steam research and mathematical calculations on steam turbines and turbine design and testing. He is a member of the A.S.M.E. Power Test Codes Individual Committee No. 11 on Complete Steam Power Plants.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tial pressure, the better will be the accuracy of the test. The throat diameter D shall be between 40 and 60 per cent of the pipe diameter. In determining the nozzle diameter and U-tube capacity when laying out a test, use formula [4], Appendix No. 2.

Low-Side Taps. There shall be two to four low-side static-pressure holes. For nozzles of 2 in. throat diameter or larger, the throat pressures holes, if any, shall be between $^1/_4$ in. and $D/8$, but not larger than $^3/_4$ in. For nozzles smaller than 2 in. throat diameter, the throat pressure holes shall be about $D/8$, but not smaller than $^1/_8$ in. All static-pressure holes must have a straight length of at least twice the hole diameter, as established by the piezometer tests of Prof. C. M. Allen and L. J. Hooper.[8]

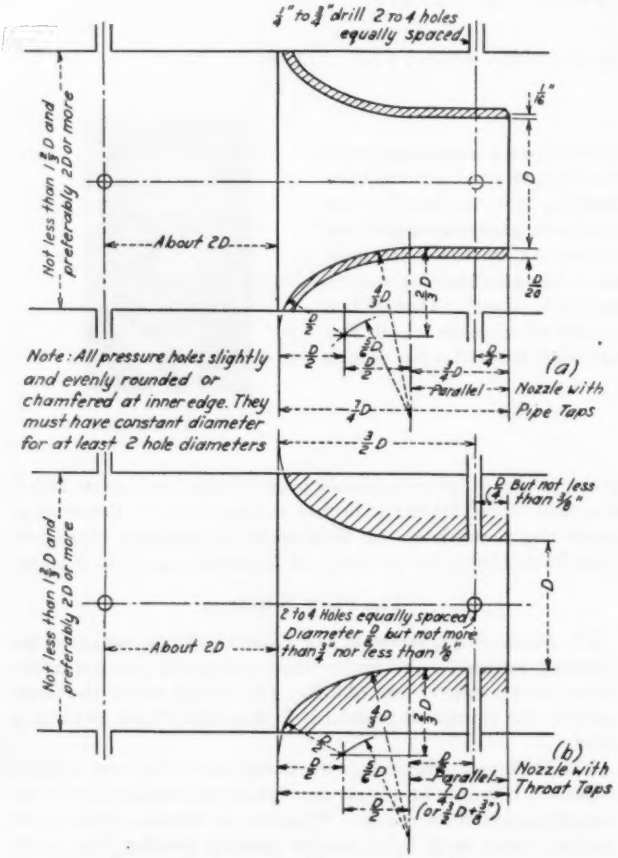

FIG. 1 DIAGRAMS OF RECOMMENDED NOZZLES

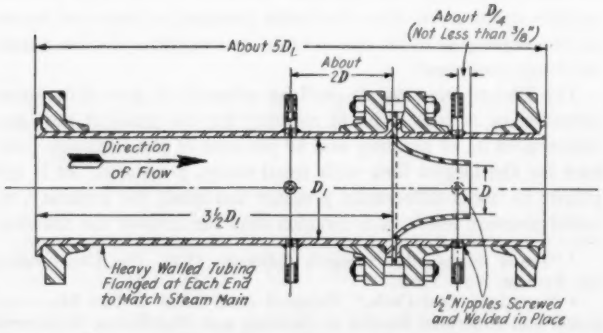

FIG. 2 PROPOSED DETAILS OF SPECIAL PIPE SECTION CARRYING NOZZLE WITH PIPE TAPS

These pressure taps shall be located about 0.25 D, but not less than $^3/_8$ in., upstream from the plane of the nozzle end. They may be arranged in either of two methods: throat taps directly in the nozzle throat, as in Figs. 1*b*, 5, 6, and 8, so as to give the actual throat pressure; or pipe taps in the pipe wall, as in Figs. 1*a*, 2, 3, 4, and 9, so as to give the pressure of the region into which the jet discharges.

When throat taps are used, special care shall be taken because of the high throat velocity to insure that the inner edges are perfectly formed. This may be accomplished by first rough-finishing the nozzle throat, drilling, reaming, and then plugging the throat holes with tight plugs, and finally finishing the throat; or the nozzle throat may be finished by grinding after the holes are drilled. In either case the inner edges of the pressure holes shall be smoothed with crocus cloth so as to remove all sharp edges and burrs. These edges should be inspected with a magnifying glass.

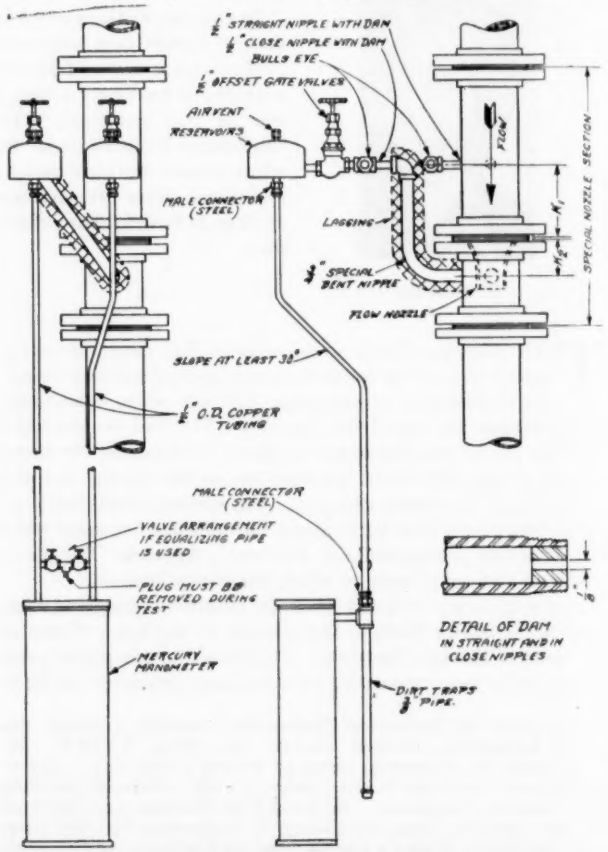

FIG. 3 PROPOSED SET-UP WITH PIPE TAPS FOR VERTICAL STEAM MAIN

When low-side pipe taps are used, the same rule in regard to length of hole shall be followed. Ordinary care to insure that the inner edges of the holes are slightly and evenly rounded or chamfered is sufficient.

The Nozzle Inner Surface shall be made of non-corrodible material, and shall have a polish which must be maintained by frequent cleaning. An important consideration is that no ripples shall be perceptible to the touch of the finger tips along the curve, its junction with the parallel portion, or the parallel portion itself. The nozzle diameter D shall be carefully measured in at least 4 axial and 4 radial places by means of an inside micrometer or carefully fitted inside gages measured by an outside micrometer. The various measurements must agree within about $D/1000$, but preferably within about 0.001 in.

[8] "Piezometer Investigation," by Charles M. Allen and Leslie J. Hooper, Trans. A.S.M.E., 1931, paper HYD-54-1.

Straight Pipe Preceding Nozzle. An essential item for smooth flow through a nozzle is a proper length of preceding straight pipe. One of the important items of the present work was an investigation of the actual distances at which a disturbance in the preceding pipe would affect the nozzle flow, given in Appendix No. 1. A rule previously given is that a nozzle should be preceded by 10 nozzle diameters of straight pipe in case of a preceding symmetrical irregularity such as a change in diameter, and by 20 nozzle diameters in case of an unsymmetrical irregularity, such as an elbow or tee. The conclusion is that this rule is conservative and should be followed if possible. However, if this is impossible, the lengths of straight pipe shall never be less than 8 and 16 nozzle diameters, respectively. The nozzle should be well centered with the preceding pipe, and care should be taken that gaskets do not extend into the nozzle opening.

A gate valve partly closed for controlling pressure gives serious irregularity and is not permissible unless it is about 200 D (not necessarily straight pipe) ahead of the nozzle or followed by a device for equalizing the steam flow such as a steam separator or other chamber. A globe valve wide open or partly closed was found to be an ordinary unsymmetrical irregularity, whether in a straight run or followed by an elbow or tee.

Valve and bend combinations occasionally occur which cause vortical motion which may give large errors. These may be eliminated by use of an egg box or straightener of some kind. It is probable that the error due to a vortex will always be so large as to indicate when a straightener is needed. However, some engineers may prefer to use a straightener in the pipe preceding the nozzle in every case.

Two to four high-side static-pressure holes with straight length of at least two hole diameters shall be provided in this pipe at a distance of about 2 D from the nozzle. The inner edges of these holes shall be slightly and evenly rounded or chamfered. The pipe diameter shall be measured in the plane of the holes to within about 0.01 in.

The straight pipe preceding the nozzle and for a short distance beyond the nozzle, as well as the nozzle itself, shall be well lagged.

The piping should be arranged so that the nozzle can be removed after a test and a filler substituted, which should always be done.

Special Nozzle Pipe Section. A section of bored pipe as in Fig. 2 may be arranged for insertion in the pipe line especially for the flow-nozzle test. This shall have a straight length of three to four pipe diameters on the inlet side of the nozzle, and one or two pipe diameters on the discharge side. The two to four sets of static-pressure holes shall be arranged in the special section as shown in Fig. 3 for vertical and in Fig. 4 for horizontal installations of the steam pipe.

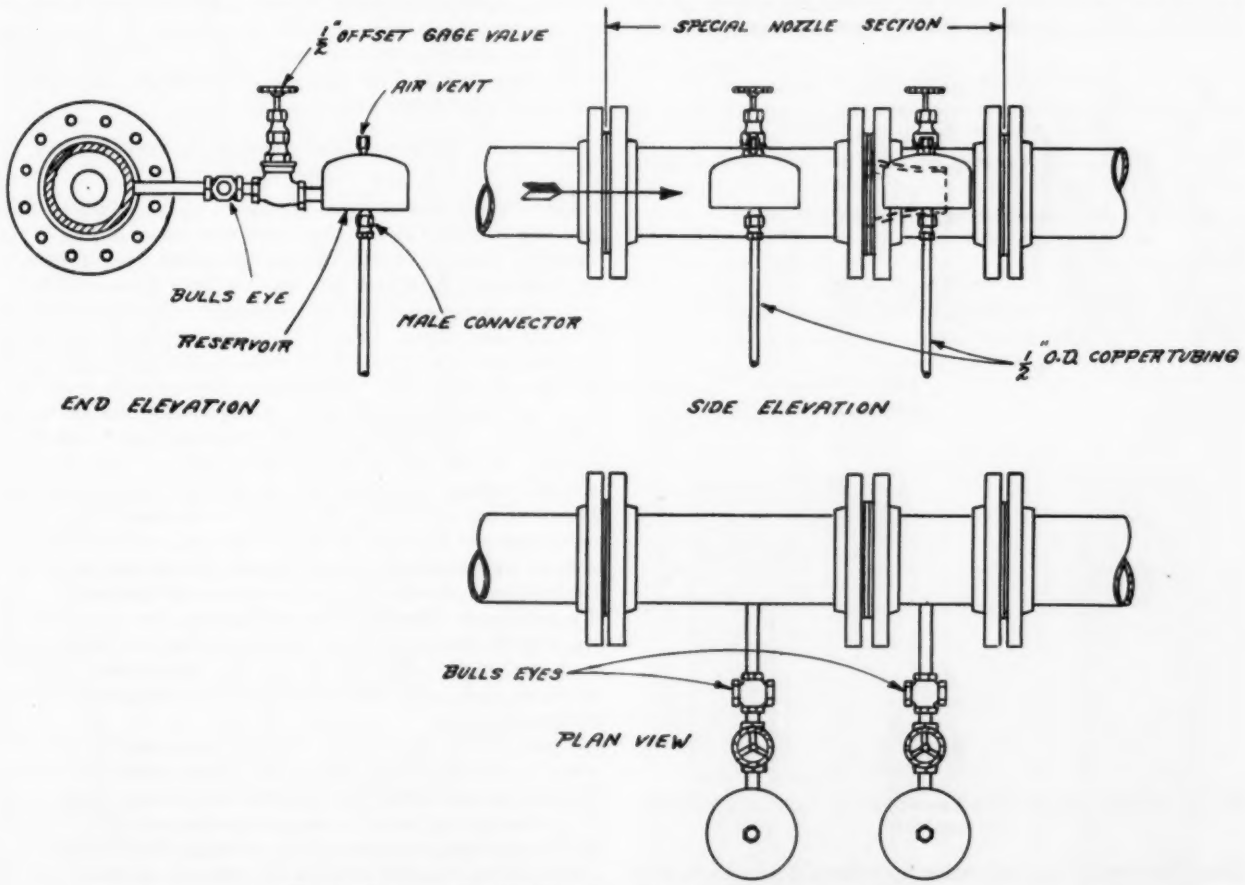

FIG. 4 PROPOSED SET-UP WITH PIPE TAPS IN HORIZONTAL STEAM MAIN

The pipes shall be bored accurately to size after the pressure nipples have been welded in so as to remove any irregularities in the pipe surface as well as to insure that the two or more sets of static-pressure connections will have identical finish one with the other as to hole edge, sharpness, etc. After the pipe has been bored, these holes shall be carefully inspected and wire edges or other irregularities removed as stated earlier under "Low-Side Taps."

The nozzles shall be doweled or otherwise secured in place in such a way that the center line of the nozzle throat coincides with

the center line of the pipe. A small amount of eccentricity of the nozzle in the nozzle pipe may produce errors of considerable magnitude, so that there is necessity for very accurate centering of the nozzle in the measuring section.

When such a special section is used, the nozzle discharge coefficient may be determined by a calibration of the complete special section, in a laboratory, with weighed flow, and with the static holes and all details exactly as in the test.

Nozzle Discharge Coefficient. This is the ratio of the actual flow to the theoretical flow, computed by a rational formula such as discussed in Appendix No. 2.

Values are given on curve 3, Fig. 10, and on Fig. 13 for a considerable range of conditions, and as the system becomes used, a complete body of coefficients will become established. Until such time as the nozzle discharge coefficients are completely established, there must be a calibration by weighed flows of each new nozzle.

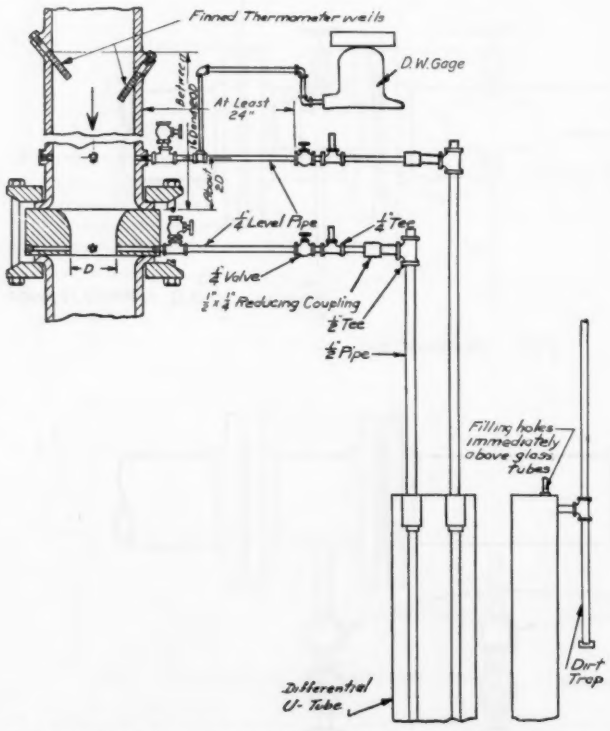

FIG. 5 SET-UP USED IN LYNN TESTS (THROAT TAPS) FOR VERTICAL STEAM MAIN

When throat taps are used, the nozzle discharge coefficient is the same as that of a nozzle freely discharging into the atmosphere or other large region. With a rational flow formula such as prescribed in Appendix No. 2 the coefficient is very nearly a true friction coefficient, and its value is nearly 0.99 over a wide range of velocities. When pipe taps are used the coefficients are slightly lower, due to greater magnitude of the differential pressure. This is because of partial evacuation of the region back of the nozzle end owing to entrainment by the nozzle jet of the surrounding fluid. In either case the coefficients derived from a calibration are reproducible with accuracy.

INITIAL TEMPERATURE AND PRESSURE

Initial Temperature. The system as thus far developed applies only to cases where the steam preceding the nozzle is superheated.

The temperature shall be measured by two mercury-in-glass thermometers inserted in finned wells, arranged and calibrated as specified in the A.S.M.E. Test Code, or by an equivalent system such as thermocouples or resistance thermometers competently handled. These shall be located in the pipe ahead of the nozzle at distances from it of not less than 16 D and preferably 20 D. Wells in a vertical run shall be inserted at an angle of about 45 deg. The general arrangement is shown in Fig. 5.

High-Side Gage Pressure. There shall be at least two accurate gages for measurement of the high-side static pressure connected to separate pipes for pressure measurement leading from the high-side static-pressure holes, or to independent static-pressure holes in the same plane. In the Lynn tests reported herewith deadweight gages were used as described in Appendix No. 1. However, carefully calibrated Bourdon gages or mercury manometers are permissible with especial precautions to insure that steam does not enter them and with correction for water column in the pressure pipe. All high-side gage-pressure pipes shall be filled with water before connecting the gages.

PIPES AND GAGES FOR MEASUREMENT OF DIFFERENTIAL PRESSURE

Lynn Piping Method. One scheme of piping which may be used was employed in the Lynn tests and shown in Fig. 5. It comprises $^1/_4$-in. pipes, carefully cleaned before erecting, extending horizontally from each pressure hole for a distance of 36 in. or more to insure a constant level of water. These pipes include blow-offs and unions. In each $^1/_4$-in. pipe, at least 24 in. from the main line, is a valve. Each valve shall be wide open all of the time during a test. Immediately beyond each valve is a $^1/_4$-in. tee with the branch hole pointing upward, for use in the initial filling. After filling and before starting a test, each tee is plugged. At the end of each $^1/_4$-in. pipe is a $^1/_4$-in. $\times$ $^1/_2$-in. or $^3/_4$-in. bushing or reducer, and then a $^1/_2$-in. or $^3/_4$-in. tee with the branch hole horizontal, one run hole being plugged and pointing upward and the other pointing downward, and connected by $^1/_2$-in. or $^3/_4$-in. vertical or slanting pipe to the differential U-tube. The horizontal pipe shall always be made truly horizontal by use of a good level. Slanting pipe shall have a slope of at least 10 deg. with the horizontal, and if between 10 deg. and 30 deg. shall be at least $^3/_4$-in. Between 30 deg. and vertical the pipe shall be at least $^1/_2$-in. To avoid leaks, the use of compression fittings is often desirable.

A great deal of care shall be taken to insure that the pipes for pressure measurement are filled with air-free water before a test. When the arrangement of Fig. 5 is used, filling is done from a small tank, using distilled water, which provides some head for flushing out air and which prevents air from entering with the water.

After filling, the deflections of the mercury columns shall be measured and compared with the vertical distance, if any, between the levels of the high-side and low-side static-pressure holes, divided by 12.6, the difference between the specific gravity of mercury and water. A maximum variation of 0.03 in. is allowed between the observed zero and the calculated zero due to difference of level. However, the calculated zero due to the measured difference in level, if any, shall be used in working up the tests.

When steam is on the main line, each horizontal pipe will be hot for a few inches next to the main, but each vertical or slanting pipe should always be cold, showing that it is filled with water.

If for any reason the valves in the pressure lines are shut off following a test, the plugs in the filling tees next to the valves should be removed if steam pressure is left on the line, because a leak through a valve seat on one side and a leak to atmosphere on the other side of the differential U-tube will result in a continuous displacement of the mercury column, with a possible loss of mercury and breaking of the glass if steam enters the U-tube.

Reservoir Piping Method. Fig. 3 for vertical and Fig. 4 for

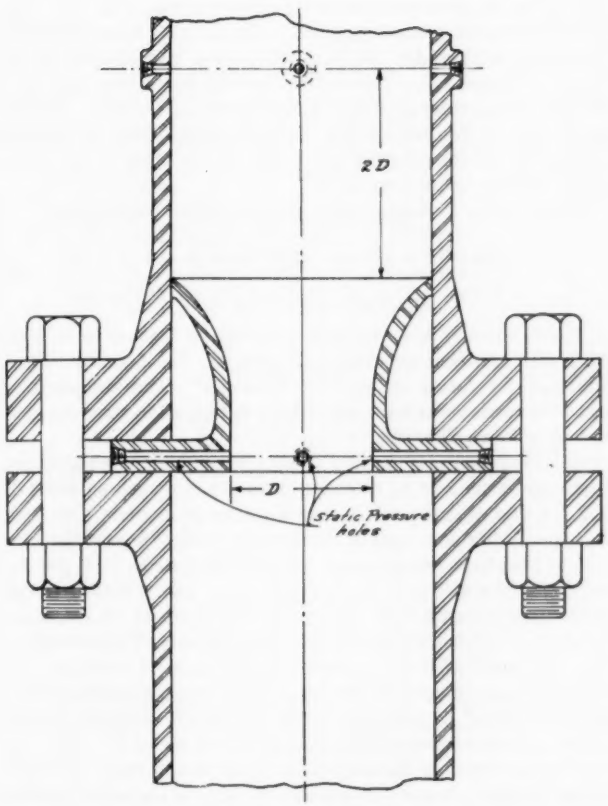

FIG. 6 PROPOSED OPTIONAL ARRANGEMENT OF NOZZLE WITH THROAT TAPS

horizontal installations show a method which may be used for connecting the nozzle to the manometer with reservoirs for condensing the steam. This arrangement is so made as to maintain equal water legs over the manometers at all times. As will be noted, the special nozzle pipe or the straight-line piping is equipped with one straight and one bent nipple for differential-pressure measurement in the case of a vertical installation. The purpose of the $^1/_4$-in. bent nipple is to bring the lower reservoir up to a level with the one connected on to the straight nipple as shown in Fig. 3. The bent nipple shall be well lagged to prevent condensation collecting therein. At the inlet end of the straight nipple shall be placed a dam having a $^1/_8$-in. hole, this hole being flush with the inside wall of the special pipe section. At the inlet end of the close nipple immediately following the bent nipple shall be placed a dam of similar construction. Following these nipples shall be placed a bull's-eye composed of crosses fitted with heavy Pyrex glass. The purpose of the bull's-eye is to visualize the exact water head on the differential manometer, and thus to render certain the fact that the water heads on the manometer are of equal height. With this method, filling is done by condensation, after blowing out the piping with steam.

Offset gate valves and reservoirs of a volume at least equal to that of the volume of the manometer tubes, complete the assembly.

One-half-inch O.D. copper tubing together with steel compression fittings may be used as the connecting tubing between the nozzle pipe and the manometer. The pitch or slope in the connecting tubing between the nozzle pipe and the manometer shall be at least one inch per foot, and preferably as nearly vertical as possible. It shall contain no sags or pockets at any point.

Piping Details. When proper precautions are taken there will be no leaks in the pressure pipe after the first assembly. Leaks in the pressure pipe shown by drops of water or a steam blow must be stopped before any tests are made.

An important point is that each pipe shall be extended downward at least 15 in. beyond the connection to the U-tube with a removable cap at the bottom. This provides that the U-tube connection is taken off the side of the pipe, and gives a dirt trap which has been found necessary in keeping the mercury columns clean. With some kinds of U-tubes, this is also very useful when cleaning the tubes without dismantling, because water can be forced through the U-tubes from the pressure pipe above, displacing the mercury and the dirt which collects in the dirt trap and is drained out by removing the cap at the bottom of the trap.

The pressure pipe may or may not contain an equalizing connection between the high and low sides. The use of such a connection may render the system more flexible.

If this connection is used during turbine performance tests, it shall be fitted with two valves on either side of a bleeder tee. This tee will be plugged when the piping is being filled, but the plug shall be removed after the valves are closed and during a test. Any leak through either valve will be disclosed by seepage of water from the open tee. Such leaks must of course be stopped.

If an equalizing connection is not used, easily arranged precautions must be taken to have the two valves in each pair of pressure pipes always opened before steam is turned on the main line, to avoid any chance of blowing mercury out of the differen-

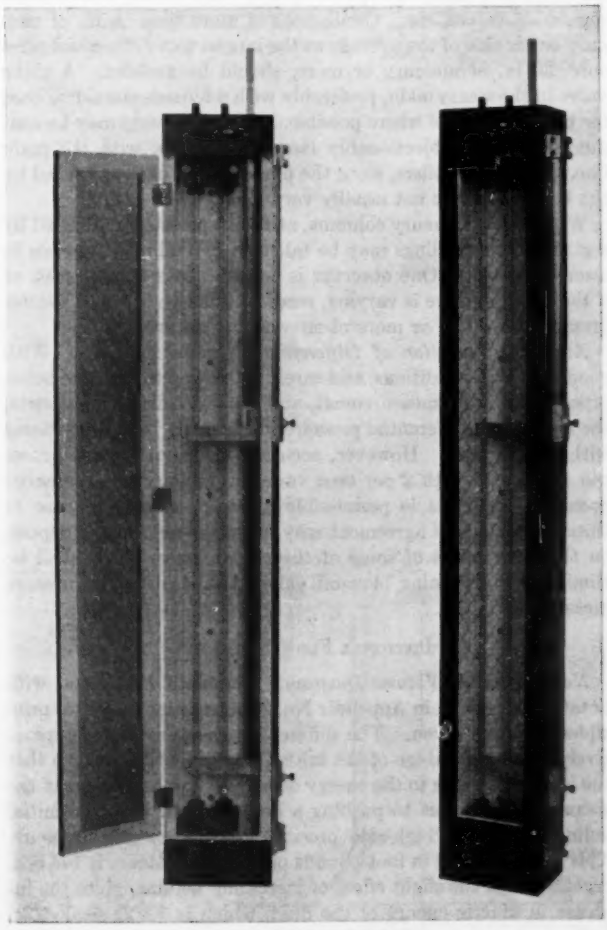

FIG. 7 DIFFERENTIAL U-TUBES FOR HIGH PRESSURE USED IN LYNN TESTS

tial U-tube. If, however, the valves have been closed for repairs of any kind, they should be opened cautiously while watching the mercury U-tube, by first cracking one, then the second, then opening the first valve a little, and then the second, etc.

Differential Mercury U-Tubes. U-tubes for this work shall be accurate to about 0.01 in. of mercury, which necessitates the use of sliders of some type. The type used in the Lynn tests is shown in Fig. 7. Definite sliders are provided with plates in front of and behind the mercury columns which can be sighted across the top of meniscus. Further details are given in Appendix No. 1. An optional equipment is a single-leg mercury column with a reservoir at the base, if the method for measuring the height of the column above the variable level in the reservoir is completely verified. Often the only way to do this will be by comparison with a two-legged U-tube such as described in Appendix No. 1, for the full-scale range.

The zero readings of the mercury U-tubes must be verified before connecting up; and again in place after filling with water.

Conduct of Test

Tests shall be conducted according to the general procedure outlined in the A.S.M.E. Turbine Test Code, particularly Pars. 67–72. Pressure fluctuations in the steam main are more objectionable in a flow-nozzle test than in a weighed-flow test because they set up oscillations of the differential mercury columns. Tests should therefore be made with the turbine governing valves blocked. Special study also should be made to reduce pressure fluctuations from other sources, such as other turbines or engines, regulating valves, etc. Oscillations of more than $^1/_2$ in. of mercury either side of the average at the largest test differential pressure, 30 in. of mercury or more, should be avoided. A globe valve in the steam main, preferably with a bypass, should be used for pressure control where possible. However, tests may be conducted without objectionably large oscillations, with the main line open to the boilers, since the pressure fluctuations caused by the boiler itself are not usually very great.

With steady mercury columns, and with pressure controlled by a globe valve, readings may be taken at five-minute intervals in a one-hour test. One observer is ample. In a shorter test, or if the main pressure is varying, readings shall be taken at shorter intervals, and two or more observers may be needed.

Allowable Variation of Differential-Pressure Readings. With good approach conditions, and careful attention to pressure holes, pipes for pressure measurement, and other details of the system, the two to four differential pressures can usually be made to agree within 1 per cent. However, accuracy sufficient for most cases can be secured with 2 per cent variation among the differential pressures, and this is permissible in many cases. In case of throat taps, lack of agreement may mean the presence of deposit on the inner edges of some of the throat holes. This shall be eliminated by opening blow-off valves in the pipes for pressure measurement.

Rational Flow Formula

Nozzle Pressure-Volume Diagram. Complete deductions, with notation, are given in Appendix No. 2, but the fundamental principles are here given. The differential pressure is a comparatively small percentage of the initial pressure. This means that the jet velocity due to the energy developed by the passage of the steam is mostly due to pushing a body of fluid with the initial volume from the high-side pressure to the low-side pressure. This energy, which in foot-pounds per pound of steam is $144\, v_1 \Delta$, together with the slight effect of increasing volume, gives the increase in kinetic energy of the fluid, which is $V^2/2g - V_1^2/2g$.

One way to present this matter is to consider the work done by the passage from high-side to low-side pressure as given by the area of a diagram on a pressure-volume plane, Fig. 16. The large rectangular area corresponds to the energy $v_1 \Delta$, and the small triangular area under the isentropic curve corresponds to the energy of expansion. This means that the major item needed in the theoretical computation of flow is the initial volume. Recent work by J. H. Keenan and the A.S.M.E. Committee on Thermal Properties of Steam[9] establishes this initial volume for steam under modern conditions of use.

Terms of the Formula. The final formula comes out as

$$w = \frac{1890 c D^2 [1 + 2\,\alpha(t_1 - t_s)]\sqrt{p_1\,\Delta\,(1 - 1.17\,\Delta/p_1)}}{\sqrt{p_1 v_1}\,\sqrt{1 - (D/D_1)^4 + 1.562\,(D/D_1)^4\,\Delta/p_1}} \quad . . [3]$$

This is a nearly exact formula and may be used up to $\Delta/p_1 = 0.10$ with an accuracy given in Appendix No. 2, under "Final Formula for Small Differential Pressure." The computation must be carried out with logarithms, a long slide rule, etc. and not by a 10-in. slide rule.

In formula [3], w is the flow in pounds per hour, c is the nozzle discharge coefficient to be taken from a curve such as curve 3, Fig. 10, and D is the cold nozzle diameter in inches. The term $2\,\alpha\,(t_1 - t_s)$ takes account of the slight increase of nozzle diameter due to the steam temperature. Under the radical, p_1 is the absolute initial static pressure in lb per sq in., and Δ is the average differential pressure in lb per sq in. The term $(1 - 1.17\,\Delta/p_1)$ is a factor which very accurately takes account of expansibility. The constant 1.17 is $3/2n$,where n is an empirical constant. In previous work n has been the exponent of the approximate isentropic curve pv^n = constant, but in our work it is merely an empirical constant whose value is determined so as to make our formula give results agreeing with values taken from Keenan's Steam Tables. In the denominator of [3], v_1 is the initial specific volume in cu ft per lb taken from the Steam Tables. The remaining radical in the denominator is a correction factor to take account of the velocity of approach in the pipe where p_1 is measured.

Appendix No. 1

EXPERIMENTAL BASIS OF THE FLOW-NOZZLE SYSTEM

The system outlined in the body of this paper is the result of recent experience gained during tests with steam nozzles which are described in this Appendix, in addition to many years' work with air as previously stated. These steam tests were made with seven nozzles. Four of them, a 4-in. × 2.20-in. (58 per cent diameter ratio), a 6-in. × 3.12-in. (51 per cent), an 8-in. × 3.67-in. (46 per cent), and an 8-in. × 4.17-in. (54 per cent), shown on Fig. 8, were tested at Lynn using throat taps. Three, a 3-in. × 1.38-in. (46 per cent), a 3-in. × 1.69-in. (56 per cent, and a 6-in. × 3.55-in. (58 per cent), shown on Fig. 9, were tested at Ohio State University with both water and steam, using low-side pipe taps.

Lynn Tests—With Throat Taps

The 4-in. × 2.20-in. nozzle was located in a downward run of pipe, with 82 in. of straight pipe ahead and 80 in. following. The pipe and nozzle were well lagged. Pressure was held at 215 lb abs by hand manipulation of a globe valve about 20 ft ahead of the nozzle. Temperatures were read on calibrated mercury-in-glass thermometers in finned wells, one 84 in. ahead of and one 42 in. after the nozzle. Superheat was taken as the steam was delivered by the boilers, varying from about 50 F to 100 F at different times. The variation during each test, however, was small. Initial pressures were first read at 4 in., and 16 in. ahead of the nozzle, and as no difference was discernible, 4 in., or $2D$,

FIG. 1b 6x3" TEST NOZZLE

FIG. 8 NOZZLES USED IN LYNN TESTS (THROAT TAPS)

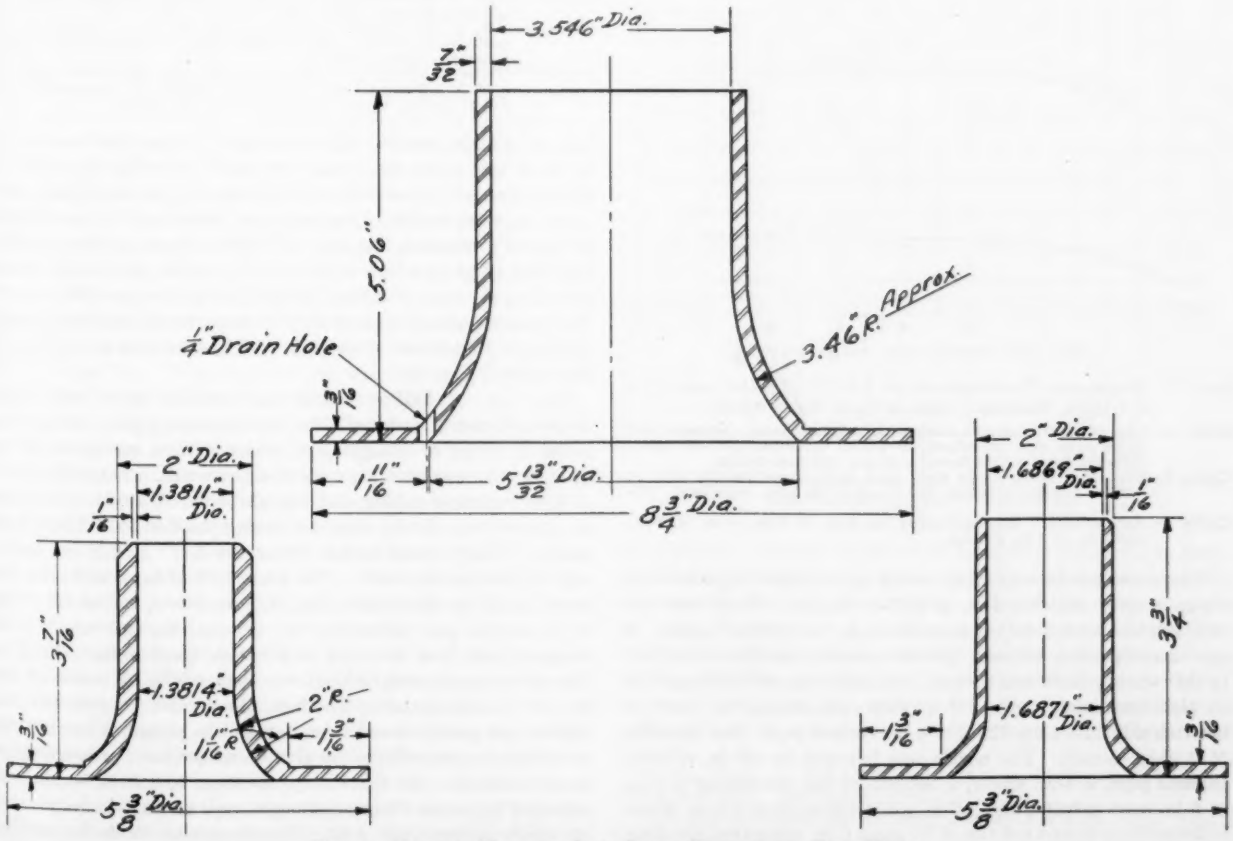

FIG. 9 NOZZLES USED AT OHIO STATE UNIVERSITY (PIPE TAPS)

was adopted as a standard. The steam after passing through the nozzle was condensed in a surface condenser and weighed. Following the flow nozzle and preceded by about 100 in. of straight pipe was a nozzle called the "plate" nozzle, designed for pressure ratios greater than the critical value. Twenty-seven tests were made with weighed flows, thus calibrating the plate nozzle. Twenty other tests were made without weighing the flow, which was calculated from the plate-nozzle readings. The tests extended over a period of about a year. In different tests, two, three, or four differential pressures, usually the latter, were read and averaged. The pressure connections were practically as shown on Fig. 5. See curve 1, Fig. 10.

The 6-in. × 3.12-in. nozzle was first tested in the steam main ahead of a turbine on which weighed-flow steam-rate tests were made. The nozzle was located in a well-lagged downward run of nominal 6-in. high-pressure pipe. Pressure was controlled by a globe valve well ahead of the nozzle. Eighty-two in. of straight pipe preceded the nozzle. At the top of the run was a 6-in. tee containing a thermometer well. Following the nozzle was a 32-in. length of 6-in. pipe, followed by a 6-in. × 8-in. adapter flange, an 8-in. elbow, and a short run of 8-in. horizontal pipe containing a thermometer well and leading to the turbine. Two differential pressures were read. Only four test points were taken, and no time was available for elimination of possible defects in the set-up. The results, therefore, are not considered as reliable as later tests on the same nozzle, described below, but are a fair check on them. See curve 4, Fig. 11.

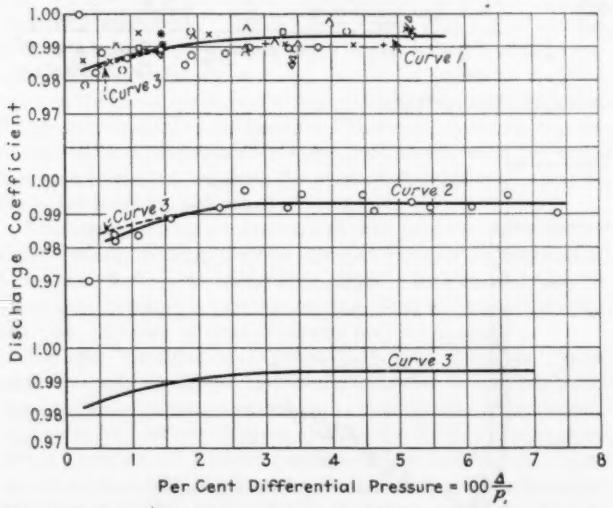

FIG. 10 DISCHARGE COEFFICIENTS OF 4-IN. × 2.20-IN. AND 6-IN. × 3.12-IN. NOZZLES—THROAT TAPS (LYNN TESTS)

Curve 2—6-in. × 3.12-in.-nozzle tests with flows based on the 4-in. × 2.20-in. nozzle; pressure, 110 lb per sq in. abs; superheat, 105–115 F.

Curve 3—Recommended standard curve for 4-in. × 2-in., 6-in. × 3-in., and 8-in. × 4-in. nozzles.

The same nozzle was later tested in a special experimental set-up in series with the 4-in. × 2.20-in. nozzle. Flows were not weighed, but were obtained from the 4-in. × 2.20-in. nozzle. A careful comparison between the two nozzles was thus obtained. In this set-up, there was a short horizontal run of well-lagged 4-in. pipe containing a gate valve (wide open during the tests), a tee with side outlet up, 72 in. of 4-in. vertical pipe, then the 4-in. × 2.20-in. nozzle. The nozzle was followed by 56 in. of 4-in. vertical pipe, a 4-in. elbow, a horizontal run containing a 4-in. × 6-in. cone reducer, and a 6-in. globe valve, then a 6-in. elbow followed by a downward run of 55 in. of 6-in. pipe, then the 6-in. × 3.12-in. nozzle, followed by 80 in. of 6-in. pipe. There was finally an elbow, a 6-in. globe valve, and a pipe run leading to a condenser. Pressure ahead of the 4-in. × 2.20-in. nozzle was controlled by a globe valve in the main steam line about 100 ft ahead of the nozzle, and a $1^1/_2$-in. bleeder in the tee just preceding the nozzle. The 6-in. globe valve between the two nozzles was adjusted for each test point to give the proper pressure on the

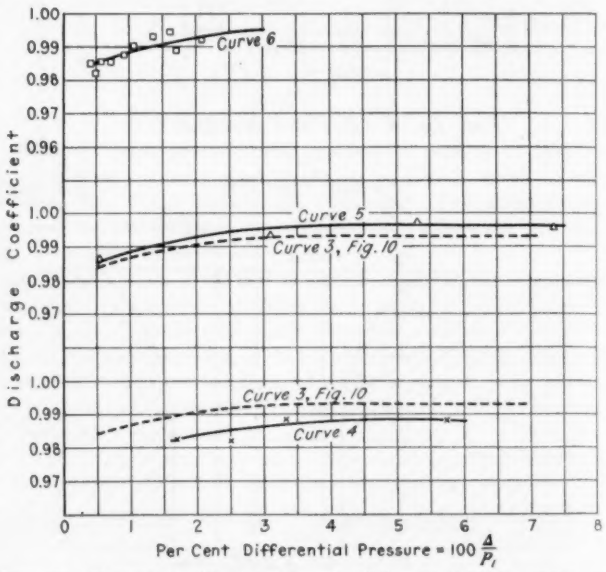

FIG. 11 DISCHARGE COEFFICIENTS OF 6-IN. × 3.12-IN., 8-IN. × 3.67-IN., AND 8-IN. × 4.17-IN. NOZZLES—THROAT TAPS (LYNN TESTS)

Curve 4—6-in. × 3.12-in. tests with weighed flows; pressure, about 210 lb per sq in. abs; superheat, 100 F.

Curve 5—8-in. × 3.67-in. tests with flows based on 6-in. × 3.12-in. nozzle and Curve 3 of Fig. 10. Pressure, 150 to 212 lb per sq in. abs; superheat, 126 F to 88 F.

Curve 6—(Same as Curve 5). 8-in. × 4.17-in. tests with flows based on 8-in. × 3.67-in. nozzle and Curve 3 of Fig. 10. Pressure, about 325 lb per sq in. abs; superheat, 85 F to 100 F.

6-in. × 3.12-in. nozzle. The amount of steam flow was varied for each test point by setting the valve following the 6-in. × 3.12-in. nozzle. Four differential pressures, 90 deg apart, were taken on each nozzle. Temperatures were read in five places: in the tee preceeding the 4-in. × 2.20-in. nozzle, in the pipe just following it, in the elbow at the top of the 4-in. pipe, in the elbow preceding the 6-in. × 3.12-in. nozzle, and in the pipe following it. The pressure ahead of the 4-in. × 2.20-in. nozzle was held at 215 lb abs and that ahead of the 6-in. × 3.12-in. nozzle at 110 lb abs. See curve 2, Fig. 10.

The 8-in. × 3.67-in. nozzle was installed in a well-lagged downward run of nominal 8-in. high-pressure pipe. It was preceded by 69 in. of straight pipe, which in turn was preceded by an 8-in. elbow, containing a thermometer well, a horizontal 8-in. × 6-in. reducing casting and 6-in. globe valve, a 6-in. elbow and an upward run of 6-in. pipe containing the 6-in. × 3.12-in. flow nozzle. Thirty-seven inches below the 6-in. × 3.12-in. nozzle was a thermometer well. The 8-in. × 3.67-in. nozzle was followed by 32 in. of straight pipe, an 8-in. elbow, and about 12 in. of horizontal pipe preceding the turbine stop valve. A thermometer well was installed just before the turbine. Flow in this case was not weighed but was determined by means of the 6 in. × 3.12-in. nozzle. The 6-in. globe valve between the two nozzles was partly closed so as to raise the pressures on the 6-in. × 3.12-in. nozzle and thus to give about the same pressure ratios on both nozzles. In this set-up, the 6-in. × 3.12-in. nozzle was preceded by about 70 in. of straight pipe and a 6-in. gate valve on which pressure was held. At the smaller flows the turbine

stop valve was partly closed so as to avoid excessive throttling on the 6-in. gate valve, since a previous experience had showed appreciable disagreement between the differential pressures due to a gate valve nearly closed. See curve 5, Fig. 11.

In the calibration of the 8-in. × 4.17-in. nozzle by comparison with the 8-in. × 3.67-in., both nozzles were set up in an 8-in. steam loop. An 8-in. horizontal globe valve, used for pressure control, was followed by an 8-in. elbow turned upward, about 93 in. of straight pipe, the 8-in. × 3.67-in. nozzle pointing up, and 24 in. of pipe after the nozzle. An elbow was followed by about 6 ft of horizontal pipe and another elbow pointing down. The downward run consisted of about 174 in. of straight pipe, the 8-in. × 4.17-in. nozzle, and 32 in. of straight pipe followed by an elbow. Four differential pressures were taken on each nozzle. Temperatures were read with mercury-in-glass thermometers inserted in mercury-filled wells, the wells being inserted through bosses in the vertical pipe at an angle of about 45 deg. The thermometer ahead of the 8-in. × 3.67-in. nozzle was 48 in. from the nozzle, and that ahead of the 8-in. × 4.17-in. nozzle was 67 in. from it. See curve 6, Fig. 11.

Discharge Coefficients With Throat Taps—Lynn Tests. The discharge coefficients for the 4-in. × 2.20-in. nozzle are shown as curve 1 on Fig. 10. The plotted points are the results of tests covering a little over a year, during which time several changes were made in the set-up and different ideas described elsewhere were tried out. Separate symbols have been used to represent the tests of each group. Each test in which the dam, shown in Fig. 12, was at least eight pipe diameters away from the nozzle, or removed entirely, has been plotted.

As was expected, based on experience with air nozzles, the average coefficient was very nearly 0.99 over a wide range of pressure ratios. All but one of the points will be seen to fall within a band of plus or minus one per cent from the average. The lowest flows represent differential pressures as small as one inch of mercury. The actual readings were about 2 in. due to the zero deflection, which increased the reading. At very small deflections the mercury columns were practically motionless, while with large deflections there was oscillation up to about one per cent. This tended to equalize the accuracy of the readings at small flows so that there is scarcely any more scattering of points at small than at large flows. Damping owing to a restriction at the bottom of the U-tube, was not considered necessary.

A few readings were taken of impact pressure with a standard impact tube at the center of the nozzle mouth and pointing upward. This was read as a differential against the throat pressure. There was about three inches of vertical length, which caused the readings to be ragged because of boiling in the tube and an unknown water leg. This impact tube was therefore abandoned and no coefficients so derived have been plotted.

The later tests on the 6-in. × 3.12-in. nozzle with the experimental set-up are given as curve 2 of Fig. 10. They show practically the same discharge coefficients as the 4-in. × 2.20-in. nozzle except at very small differential pressures where the discharge coefficient is very slightly lower.

Curve 3 of Fig. 10 has been made up from curves 1 and 2, giving slightly more weight to curve 1. Curve 3 has been shown dotted on curves 1 and 2 of Fig. 10, and on curves 4 and 5 of Fig. 11, for comparison.

The original weighed-flow tests on the 6-in. × 3.12-in. nozzle and the 8-in. × 3.67-in. tests obtained by comparison with the 6-in. × 3.12-in. nozzle, both in commercial set-ups, are shown as curves 4 and 5, Fig. 11. The test points were obtained with but two differential U-tubes, and for this and similar reasons were not given the same weight as the tests shown on Fig. 10. They are, however, a fair check on the standard coefficient curve 3 of Fig. 10.

The comparative tests on the 8-in. × 3.67-in. and the 8-in. × 4.17-in. nozzles are shown on curve 6, Fig. 11. The curve drawn through the points is the same as curve 5. Flows were calculated from the readings of the 8-in. × 3.67-in. nozzle and curve 5. The 8-in. × 4.17-in. coefficients were based on the readings of the 8-in. × 4.17-in. nozzle and the flows calculated from the 8-in. × 3.67-in. nozzle. The tests showed no perceptible difference between the two nozzles, although the ratio of nozzle to pipe diameter was slightly different, being 0.46 for the 8-in. × 3.67-in. nozzle and 0.54 for the 8-in. × 4.17-in.

Ohio State University Tests—With Low-Side Pipe Taps

In these tests, the 3-in. × 1.38-in., the 3-in. × 1.69-in., and the 6-in. × 3.55-in. nozzles (Fig. 9) were tested with both steam and water. The set up and tests are described in two papers, the 6-in. × 3.55-in. in a paper by Professors Beitler and Bucher,[10] and the 3-in. nozzles in a paper by Messrs. Beitler, Bucher, and Barnes.[11]

In the steam tests the 3-in. × 1.38-in. and the 3-in. × 1.69-in. nozzles were preceded by about 135 diameters of straight pipe

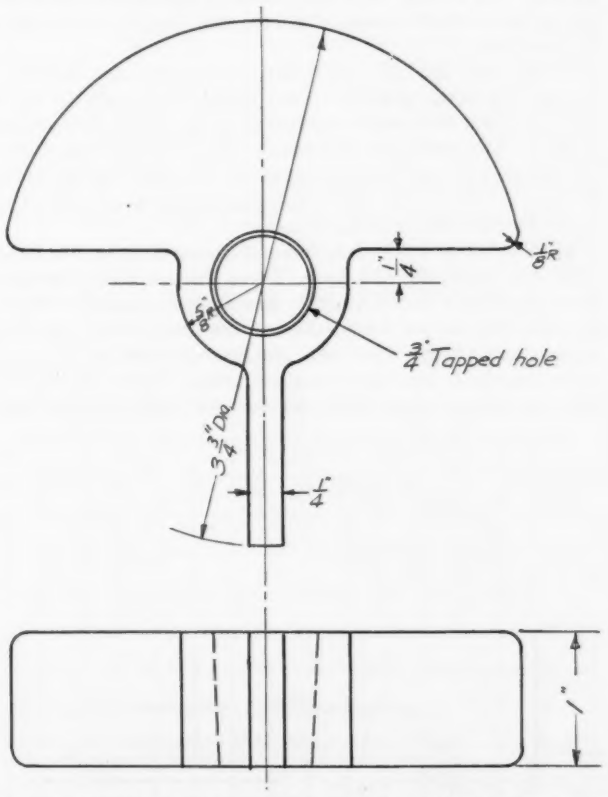

Fig. 12 Dam Used in Tests of 4-In. × 2-In. Nozzle to Simulate Pipe Irregularity (Lynn Tests)

and the 6-in. × 3.55-in. by about 64 diameters, which was in turn preceded by straightening vanes and the hand pressure control, an angle globe valve. The static high-side pressure was measured one pipe diameter ahead of the nozzle, by means of mercury manometers which were connected to the steam line through reservoir assemblies described in the papers and similar to those shown in Figs. 3 and 4. A 50-in. manometer was used for the tests at 19 lb abs, and a special mercury manometer of approxi-

[10] "The Flow of Fluids Through Orifices in Six-Inch Pipes," Trans. A.S.M.E., 1929, paper HYD-52-7a.

[11] "A Study of Primary Metering Elements in 3-In. Pipe," read before the A.S.M.E., Dec., 1931.

mately the same construction but capable of measuring pressures up to 117 lb per sq in. for the tests at 65 lb abs.

The low-side pressure connection was located in the pipe wall in accordance with the method shown in Fig. 1*a*. Owing to the great length of the preceding pipe, and the fact that the low-side taps of this method show a high degree of uniformity, only one differential pressure was taken. The differential pressure was measured by a mercury-filled inverted water manometer, approximately 10 ft in length. The top of the manometer was connected to a high-pressure air line, so that the manometer pressure could be adjusted to approximately the same pressure as that in the steam main. The bottom of the manometer was connected to the static-pressure connections in the steam pipe by means of $^1/_2$-in. O.D. copper tubing and special fittings.

The temperature of the steam was controlled by the rate of firing of an independent superheater. Temperature was measured by a mercury-in-glass thermometer in a finned A.S.M.E. well located 5 pipe diameters ahead of the nozzle. This well could be withdrawn while pressure readings were being taken. Mercury was usually the transfer medium in the well, but cylinder oil was sometimes used. Solder was used at the highest temperatures.

In the steam line after the nozzle, a valve was used to control the pressure in the test line. After passing the nozzle the steam was condensed in a surface condenser having 465 sq ft of cooling surface. The condenser was fitted with a wet vacuum pump. The condensate was first discharged into an open overhead tank for removal of air, and then weighed by means of double weigh tanks on calibrated platform scales.

The steam line was usually warmed up for three or four hours before the beginning of a test. When the line was thoroughly warmed, the flow was adjusted to give approximately the desired pressure drop across the nozzle, and the line pressure adjusted to the desired value. Not until the pressures and temperatures were stabilized, were any readings taken. After the desired pressures were set and the temperature was being adjusted, care

FIG. 14 8-IN. × 4.17-IN. STEAM-FLOW NOZZLE INSTALLED, WITH LAGGING REMOVED

was taken to remove all air from the manometer connections, and the water in the manometer tubes was cooled to approximately room temperature. The minimum length of run was 30 min of steady readings and the maximum 90 min. In each case the length of the run was sufficient to get at least two tanks of water, each tank containing 225 lb. At least 20 readings were taken during each run. In the longer tests, readings were taken at two-minute intervals. Two observers taking all readings simultaneously were used in all these tests.

Discharge Coefficients With Pipe Taps—Ohio State University Tests. The discharge coefficients for the three nozzles tested are shown in Fig. 13. It will be noted that the coefficients are somewhat lower than those obtained in the Lynn tests. This is due to the use of low-side pipe taps instead of throat taps, as explained earlier in the paper under "Nozzle Discharge Coefficient." Regardless of the absolute value of the coefficients, however, it is felt that they are reproducible within the necessary limits of accuracy.

DETAILS OF THE SYSTEM

Pipe Irregularity—Tests With a Dam. During the Lynn tests on the 4-in. × 2.20-in. nozzle, a dam shown in Fig. 12 was inserted into the pipe ahead of the nozzle through the tee at the top of the run, and readings were taken with the dam at varying distances from the nozzle. The dam closed off one side of the pipe completely, the open side having very nearly one-half the pipe area. During these tests differential pressures were taken from three of the high-side static-pressure holes to three low-side static holes, and from an ordinary and a specially designed impact tube with no vertical leg at the nozzle mouth to the No. 4 low-side static hole. The open side of the dam was directly over the No. 4 low-side hole. With the static differentials the dam caused no perceptible change in the coefficients until it was brought nearer than about 32 in., or 8 pipe diameters. When the dam was brought quite near the nozzle, the coefficients increased to values well over unity, which is easily explained since it is practically certain that the jet leaving the dam does not completely fill the pipe between the dam and the nozzle. Under this condition the average differential pressure is somewhat too small, some of the high-side static-pressure holes being in an eddy and reading lower than the actual pressure in the high-velocity jet, and the actual velocity of approach being considerably higher

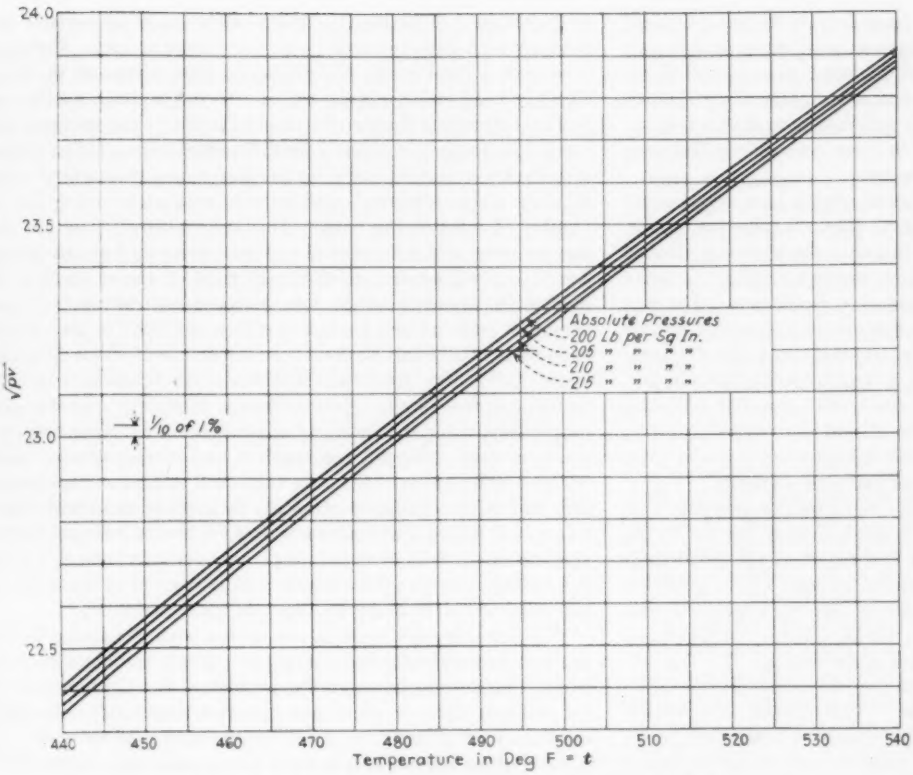

FIG. 15 $\sqrt{pv}$ PLOTTED AGAINST TEMPERATURE IN DEG F
(p = pressure, lb per sq in. abs.; v = volume, cu ft per lb; values from Keenan's "Steam Tables," 1930 edition.)

than the velocity calculated on the assumption that the pipe is full.

With the impact-tube readings the coefficients began to be affected when the dam was about 40 in. from the nozzle, and the coefficients acted irregularly as the dam approached the nozzle, first increasing slightly and then dropping off rapidly. This indicated that when the dam was brought too close the distribution of velocity over the nozzle throat was not uniform, and that the impact tube was affected by stray jets. Since it is more difficult to install than the ordinary static differential-pressure pipes, and is also subject to error due to an uncertain water leg in some cases unless specially designed, the impact tube is not recommended for use with this system. The use of static pressures requires that the velocity of approach be taken into account, which is easily done with the formula given in Appendix No. 2.

The concentration of the flow along one side of the pipe by the dam is considered to be as severe a condition as any ordinary unsymmetrical irregularity such as an elbow or tee, hence the rule of 16D following such irregularities.

A special test showed that a globe valve caused very little disturbance even when nearly closed, hence it is to be treated as an ordinary unsymmetrical irregularity. A gate valve nearly closed, however, caused the two differentials of a pair 180 deg apart to show as much as 5 per cent difference, even when followed by about 20D of straight pipe. A gate valve followed by a bend (in this case a tee) caused from 8 to 12 per cent variation between two differentials and produced an unstable condition. With the same gate valve wide open, the variation was reduced to about 1.5 per cent. A gate valve partly closed is therefore to be avoided unless very remote from the nozzle, or unless followed by special baffles or a steam separator or similar chamber.

Guide Vanes to Prevent Rotary Motion. These are often prescribed in flow-nozzle work in the straight pipe preceding the nozzle. However, it is believed that if the rules here given for lengths of straight pipe are followed, and if gate valves partly closed are avoided, rotary motion or whirls will not often be encountered. Such motion is probably due to some peculiar combination of restrictions and bends, combined with low pipe velocities. Its occurrence will be indicated by results such as large disagreement between the differential pressures, or absurd discharge coefficients. Hence guide vanes may be omitted unless trouble is experienced.

Velocity Reconversion. The present tests show that a considerable amount of the differential pressure is recovered by reconversion of the jet velocity into pressure in the pipe beyond the nozzle. Tests on the 6-in. × 3.12-in. nozzle showed practically 30 per cent recovery at a distance of 12 in. or 2 pipe diameters after the nozzle face, and 40 per cent at 22 in. or 3.7 pipe diameters. At 32 in. or 5.3 diameters the recovery was about 40.5 per cent. It

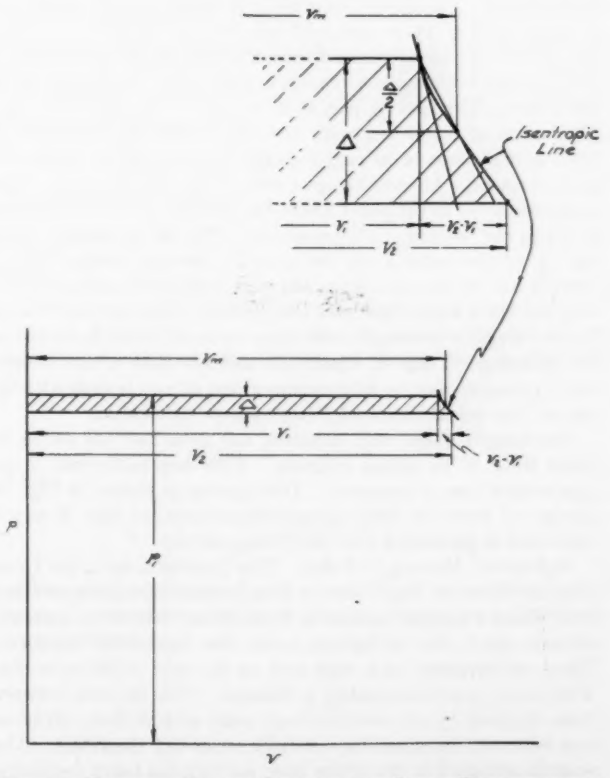

FIG. 16 PRESSURE-VOLUME DIAGRAM FOR STEAM EXPANSION IN A FLOW NOZZLE

is therefore recommended that at least four diameters of straight pipe be placed after a nozzle whenever possible, in which case approximately 40 per cent of the differential pressure will be recovered. This amount seemed to increase slightly at small flows, rising to about 43 per cent. The full-load flow in the 6-in. × 3.12-in. nozzle tests corresponded to 5 per cent differential pressure, so that the net loss was 3 per cent.

The straight pipe beyond the nozzle goes a long way toward serving the purpose of the divergent part of a venturi meter. The jet leaving the nozzle at first fills only the central portion of the pipe. It gradually expands and eventually fills the entire pipe, gaining in pressure as the velocity diminishes. The fact that reconversion is practically complete at a distance of four pipe diameters means that the effect of the symmetrical irregularity formed by the nozzle itself is not noticed after this distance. This shows that the rule given that a nozzle following an ordinary symmetrical irregularity should be preceded by about four pipe diameters or eight nozzle diameters of straight pipe, applies to a restriction of about half the pipe diameter.

Deadweight Gages. The necessity for frequent calibration of an ordinary gage by means of a deadweight gage has led to the use in the Lynn tests described in this paper, of the deadweight apparatus itself for the measurement of the initial pressure. Early research work of this character was accomplished with actual pressure measurement by use of ordinary deadweight-gage testers primarily designed for gage testing. To this apparatus was added an upper stop to prevent excess pressure from lifting the piston from the cylinder. This proved so successful that other forms of home-made apparatus have been used, finally leading to a design of deadweight pressure gage shown set up for a test in Fig. 14. Apparatus of this type has been used for all steam-research work for the last twenty-five years in the General Electric Company's Lynn Works, and has proved to be very satisfactory. The apparatus is made by mounting in stands such as shown in Fig. 14, pistons and cylinders of $^1/_8$ sq in. area purchased from a reputable manufacturer of deadweight-gage testers. In operation the deadweight gage is piped up to the point where the pressure is measured, just as in the case of the Bourdon gage. The reservoir connected with the deadweight-gage cylinder is filled with a grade of oil suited to the temperature at which the gage operates. At room temperature a light grade is used. The pipe connected to the point where the pressure is to be measured is led to the bottom of this reservoir. The oil, of course, keeps on top of the water from the pipe for pressure measurement. During use, an operator spins the gage with one hand and operates the valve which regulates the pressure with the other. The heavier weights are made with large diameter so as to facilitate the spinning. Years of experience indicate that a very nearly exact pressure may be held during a test of any length without any of the uncertainties of Bourdon-gage calibration.

Deadweight gages with constant use soon leak oil owing to slight wear of the piston cylinder. This does not result in an appreciable loss of accuracy. The apparatus shown in Fig. 14 has an oil reservoir with appreciable volume, so that it would only need to be refilled after fairly long periods.

Differential Mercury U-Tubes. The U-tubes used in the Lynn tests are shown in Fig. 7, and as already mentioned, are provided with sliders which have plates in front of and behind the mercury column which can be sighted across the top of the meniscus. These are mounted on a steel post on the side of the tube box. They are of course accurately horizontal. The distance between them is given by an accurate brass scale with 0.10-in. divisions and with 0.01 in. given by a vernier on one of the riders. The scale is attached to the lower rider so that the lower reading is always zero. The glass tube of the U-tubes has an internal bore of $^1/_4$ in., so that with clean glass there is practically no error due to uncertainty of capillarity, which often causes appreciable deflections with glass tubes of $^1/_8$ in. bore, more or less. The glass tubes are a good grade of boiler-gage glass about 48 in. long. This type of U-tube is much superior to the common variety requiring estimation by eye of a scale adjacent to the mercury column. An important item of the differential gage is the provision of a stout wooden box enclosing the glass tubes, with a front door of thick glass reinforced with wire netting and with a liberal number of holes in the back. This is for protection of the observers from scalds in case the glass breaks and steam issues. The $^1/_4$-in. valves close to the main must of course be shut off quickly in case of breakage, but the water contents of the pipes would be emptied and enough steam might issue to give a bad burn before this could be done. In the course of about 20 years' work with steam differential U-tubes, such breakage has only occurred a few times. Nevertheless it is always possible, and proper regard for the safety of the observers demands the precautions cited. Careful construction and careful manipulation of the stuffing boxes of the glass tubes will minimize glass breakage, and with reasonable attention to prevention of leaks elsewhere, will insure that cold water and not steam is always in the glass tube. It is to be noted that it is never safe to clean a glass tube with a wire or other piece of metal, inserted in the inside of the tube, as this is likely to cause the glass to shatter.

The dirt trap, described in connection with the piping to the U-tube, assists greatly in keeping the mercury column clean. It is also desirable to have the upper block of the U-tube made of chrome-iron alloy or other non-corrosive material. Otherwise, small amounts of rust from it will appear above the mercury. In spite of these precautions a little dirt occasionally accumulates in the water immediately above the mercury. This may be removed by forcing water through the U-tube from the pressure pipe above, displacing the mercury and dirt, which collect in the dirt trap and are drained out by removing the cap at the bottom of the trap. The U-tube is then refilled with mercury through holes immediately above the glass, which are afterward plugged. The pipe is then refilled with water.

Appendix No. 2

FORMULAS FOR STEAM FLOW

Notation

w = flow, lb per hr

p_1 = high-side static pressure, lb per sq in. abs

Δ = differential pressure, lb per sq in., or difference between p_1 and absolute low-side static pressure
For most work, Δ/p_1 will not exceed about 0.10. However, where the drop is not objectionable, and the Exact Formula given later is used, it may have any value up to about 0.56.

v_1 = specific volume at high-side conditions, from Keenan's 1930 Steam Tables, cu ft per lb

v_2 = specific volume at low-side conditions with isentropic expansion

t_1 = high-side temperature, deg F

T_1 = high-side temperature, deg F abs = $t_1 + 459.6$

t_s = standard temperature at which micrometer for measuring nozzle diameter is correct, usually 68 F

α = linear coefficient of expansion of nozzle per deg F = 0.0000065 for steel

D = nozzle diameter in inches as average of a number of careful measurements with a micrometer which is at approximately the temperature of the nozzle

D_1 = diameter in inches of pipe preceding nozzle where p_1 is measured

n = exponent for isentropic expansion of superheated steam,

corrected empirically for formulas [3] and [4]. n is to be taken as 1.28

V = jet velocity at nozzle exit, ft per sec

V_1 = approach velocity in pipe preceding nozzle, ft per sec

c = coefficient of discharge. With throat taps this may be taken as 0.99, unless a more accurate value is available

g = acceleration of gravity, to be taken as the standard value, 32.17 ft per sec. per sec. The actual value at any probable test location in the U. S. differs by a negligible amount. For instance, the variation at Lynn, Mass., where the tests were made, would affect the flow by about $^1/_{100}$ of 1 per cent. For any local value g_L, multiply 1890 in the formula by $\sqrt{g_L/32.17}$

Final Formula for Small Differential Pressure, up to $\Delta/p_1 = 0.10$

$$w = \frac{1890cD^2\,[1 + 2\alpha\,(t_1 - t_s)]\,\sqrt{p_1\Delta\,(1 - 1.17\,\Delta/p_1)}}{\sqrt{p_1v_1}\,\sqrt{1 - (D/D_1)^4 + 1.562\,(D/D_1)^4\,\Delta/p_1}} \quad [3]$$

For cases where Δ/p_1 is less than about 0.03, it is sufficiently accurate to neglect small terms, which gives

$$w = \frac{1890cD^2\,[1 + 2\alpha(t_1 - t_s)]\,\sqrt{\Delta(p_1 - \Delta)}}{\sqrt{p_1v_1}\,\sqrt{1 - (D/D_1)^4}} \quad [4]$$

This formula with $[1 + 2\alpha(t_1 - t_s)]$ taken as 1.00 may be used to determine the nozzle diameter in the preliminary work of laying out a test with Δ/p_1 up to 0.10.

These formulas are only for initially superheated steam. If this initial superheat is slight, it makes no difference because "undercooling" always occurs. That is, the expansion continues to follow the superheated-steam laws beyond the saturation line, and condensation does not occur when the saturation temperature is reached.

The value of $\sqrt{(p_1v_1)}$ is to be found by graphical interpolation from steam tables such as Keenan's, using a curve such as Fig. 15. The quantity $\sqrt{(pv)}$ is computed for a number of even values of pressure for values of volume given in the steam tables for a range of temperature and plotted against t. In any set of tests the initial conditions will vary somewhat from test to test, so that the curve such as Fig. 15 should cover the entire region within which p_1 and t_1 occur, with a margin on either side to give fair curves. It might be necessary to cross-plot values of $\sqrt{(pv)}$ against p for a few values of t to insure proper spacing of the curves of Fig. 15 for the various even values of p.

It has been determined by a careful investigation of volume relations in Keenan's 1930 Tables that for steam pressures less than 600 lb per sq in., the error of formula [3] is, for differential pressures of 5 per cent and less, about 0.1 of one per cent, and for 10-per cent differentials about 0.2 of one per cent; for pressures of 600 to 2000 lb the maximum error is, for 5-per cent differentials, about 0.2 of one per cent, and for 10-per cent differentials, about 0.5 of one per cent. In general the maximum errors occur near the saturation line. For high superheats the errors are smaller.

Types of Steam Formulas. The ordinary method of handling velocity due to expansion of steam is by means of a Mollier diagram on which values of total heat are read at points corresponding to the low-side and high-side pressures at the same entropy. For the small differential pressures of the present work, it is impossible to read any existing diagram with anything approaching accuracy, so that this usual method fails completely. This is the reason we must use the above formula [3]. However, this formula is limited to values of Δ/p_1 up to about 10 per cent. There is, therefore given later, beginning with the paragraph "Plan for Deduction of Exact Formula," a somewhat laborious second method of computing theoretical flow which involves fewer approximations than the method of formula [3], by making use of values from the steam tables. It is believed that this method gives accuracy with flows of any magnitude. It also gives the means by which the accuracy of formula [3] was established.

Plan for Deduction of Formula [3]. As pointed out in the paper in the paragraph "Nozzle Pressure-Volume Diagram," an approximation is used to determine the small triangular area under an isentropic curve of the pressure-volume diagram of Fig. 16 which gives no appreciable error for values of Δ/p_1 up to about 0.10. There also must be used in the formula a proper value of v_2, the final specific volume. A very common approximate procedure in this and similar matters is to assume that the isentropic expansion of steam is given by the exponential law,

$$pv^n = c$$

This leads to a well-known, rather complicated formula given later as [6], that involves fractional exponents and was first proposed by Saint Venant. There are also well-known methods of making further approximations, using the first term of an expansion in series. All of these approximations, however, leave a doubt as to the accuracy of the final formula.

We therefore next proceed to deduce from first principles an "Approximate Formula from the Exponential Law." It turns out that this is identical with the previously known formula based on approximations in Saint Venant's formula [6]. However, so many approximations are made both with the original assumption that $pv^n = c$ and in the further deduction, that we cannot be sure that we have a legitimate formula. We therefore use the formula finally found merely as an empirical form, and then proceed to find a value for n which we regard merely as an empirical constant whose numerical value is selected to give agreement with the steam tables.

Deduction of Approximate Formula From the Exponential Law. The mathematical work for this procedure will now be given. In order to find the slope of the tangent at the top of the triangular area, we differentiate

$$pv^n = p_1v_1^n$$

which gives

$$\frac{dv}{dp} = -\frac{1}{n}\,p_1^{1/n}v_1p^{-1-1/n}$$

The minus sign indicates that v decreases as p increases. This value of dv/dp with $p = p_1$ gives the slope at the top of the triangle. Making the approximation that v_2 also is given by this slope.

$$\frac{v_2 - v_1}{\Delta} = \frac{1}{n}\,\frac{v_1}{p_1}$$

Hence

$$v_2 - v_1 = \frac{v_1\Delta}{np_1} \text{ and } v_2 = v_1\left(1 + \frac{\Delta}{np_1}\right)$$

This gives, as the work in foot-pounds, corresponding to the triangular area computed from the tangent to the pv^n curve at the upper corner,

$$144\,\frac{\Delta^2v_1}{2np_1}$$

By adding to this the area of the rectangular portion of Fig. 16 or 144 $v_1\Delta$, we have as the total energy of the isentropic expansion, which, as previously specified, is the change in kinetic energy,

$$\frac{V^2}{2g} - \frac{V_1^2}{2g} = 144\left(v_1\Delta + \frac{\Delta^2 v_1}{2np_1}\right)$$

from which it follows that

$$V^2 = \frac{2g \times 144 v_1 \Delta\left(1 + \frac{\Delta}{2np_1}\right)}{1 - (V_1/V)^2}$$

Since the flow is the same in the jet and the approach pipe,

$$\frac{V_1}{V} = \left(\frac{D}{D_1}\right)^2 \frac{v_1}{v_2}$$

Using the value of v_2 approximated above from the slope,

$$\frac{v_2}{v_1} = 1 + \frac{\Delta}{np_1}$$

We can expand this by the binomial theorem and neglect high powers of the small quantity Δ/p_1 so that

$$(v_1/v_2)^2 = (v_2/v_1)^{-2} = 1 - \frac{2\Delta}{np_1}$$

Substituting this in the value of V_1/V just given,

$$1 - \left(\frac{V_1}{V}\right)^2 = 1 - \left(\frac{D}{D_1}\right)^4 \left(1 - \frac{2\Delta}{np_1}\right)$$

This we later substituted in the above value of V^2.

The flow is given by the expression

$$w = \frac{3600\pi c}{4} \frac{D^2}{144} \frac{V}{v_2}$$

(This assumes that the nozzle has the diameter D, which is not true when it is hot. A correction for this is made in the final formulas.)

From the previous values of V and v_2 we may write

$$\frac{V}{v_2} = \frac{12\sqrt{2g\Delta}}{\sqrt{1 - \left(\frac{V_1}{V}\right)^2}} \sqrt{\frac{v_1\left(1 + \frac{\Delta}{2np_1}\right)}{v_1^2\left(1 + \frac{\Delta}{np_1}\right)^2}}$$

We may expand the denominator by the binomial theorem, noting that Δ/p is a small quantity whose higher powers may be neglected, so that

$$\left(1 + \frac{\Delta}{np_1}\right)^{-2} = 1 - \frac{2\Delta}{np_1}$$

By neglecting squares of small quantities we may write the product of this with the numerator,

$$\left(1 + \frac{\Delta}{2np_1}\right)\left(1 - \frac{2\Delta}{np_1}\right) = 1 - \frac{3}{2}\frac{\Delta}{np_1}$$

By substituting this in the preceding expression for w, we arrive at a formula for flow as the result of making a number of approximations and using the exponential law namely,

$$w = \frac{3600\pi c D^2 \sqrt{2g}\sqrt{\Delta\left(p_1 - \frac{3\Delta}{2n}\right)}}{48\sqrt{p_1 v_1}\sqrt{1 - (V_1/V)^2}} \quad \ldots\ldots [1]$$

This is identical with a formula often deduced by making approximations in the well-known theoretical formula given later as [6] and involving fractional exponents, and which was first deduced by Saint Venant from $pv^n = c$.

In this formula we have used as the value of the small triangular area the value under the tangent at the upper corner, which is obviously less than the area under the isentropic curve. We have also used as the value of v_2 the value to the foot of the tangent which is somewhat less than the actual value to the intersection with the isentropic curve. It would seem that if we could use a value of n which differed slightly from the value corresponding to the index of the isentropic curve, we might make corrections for these inaccuracies and obtain a formula somewhat more exact than [1], with n as the exponent of the isentropic curve. This equation would have the same form as [1], but would use for n such an empirical value as would make the formula more nearly accurate than when the isentropic value of n was employed.

Formula With Steam-Table Volumes. In order to accomplish this we next proceed to find a formula a little more accurate than [1]. In this we use the exact value of v_2 instead of any approximation thereto. We also introduce the specific volume v_m, which is the volume on the same isentropic curve for a pressure drop $\Delta/2$. We then have as a very close expression for the area in Fig. 16,

$$\frac{V^2}{2g} - \frac{V_1^2}{2g} = 144\, v_m \Delta$$

In order to be more nearly exact, this uses as the triangular area under the curve the area under a straight line through the midpoint of the curve, instead of that under a tangent at the upper corner. We also assume the exact v_2 and not that given by the slope of the tangent.

It follows, as in the previous deduction, that

$$w = \frac{3600\pi c D^2 \sqrt{2g v_m \Delta}}{48 v_2 \sqrt{1 - (V_1/V)^2}} \quad \ldots\ldots [2]$$

This involves very little approximation. We proceed now to use it on the basis of values of v_2 and v_m from the steam tables to determine an empirical value of n in a formula of the from of [1].

Empirical Determination of "n." Equating [1] and [2] gives

$$\frac{v_m}{v_2^2} = \frac{1 - \frac{3}{2n}\frac{\Delta}{p_1}}{v_1}$$

Solving for n gives a value which makes [1] give the same result as the nearly exact formula [2],

$$n = \frac{\frac{3\Delta}{2p_1}}{1 - \frac{v_1 v_m}{v_2^2}}$$

Actual values of volumes from Keenan's Steam Tables for even pressures were plotted against entropy, and the values of v_2 and v_m read at constant entropy on curves such as Fig. 15. From these, values of n were computed from the above equation, for different values of Δ/p_1 at different parts of the steam table. It was found that n was very nearly independent of Δ/p_1, up to about 0.10, and differed but little in various parts of the steam table, so that a value of n in formula [1] of 1.28 represented to within a few tenths of one per cent the closely approximate formula [2]. As stated, this comparison involves no assumption that this value of n fits the relation pv^n = constant. However, the value of n corresponding to this equation was found as a separate item of the previous work, and was actually found to be

practically the same as the n which gave equality between [1] and [2]. This means that the approximations made in deducing Equation [1] by either of the methods cited, involve no appreciable error. However, it is important to know that we can find a value of n for Equation [1] which gives the same results as when values from the steam tables are inserted in Equation [2], which has a single evident and slight approximation. This basis is more satisfactory than previous deductions of [1] as the result of a number of approximations beginning with pv^n = constant, whether made by using a tangent to the isentropic as here worked out, or by use of approximations in Saint Venant's formula [6]. A value of n of 1.3 has been used with the latter approximation. The result is affected but little whether 1.3 or 1.28 is used. However, it is felt that 1.28 is somewhat better on the average for all parts of the steam tables.

If the value of the cold-nozzle diameter is D, the value of the square of the diameter to be used in the formula is

$$D^2[1 + 2\alpha(t_1 - t_s)]$$

Substituting all of these values in the expression [1] for w gives the final formulas [3] and [4] presented earlier.

Plan for Deduction of Exact Formula. Formulas [3] and [4] are amply accurate for all usual pressures with Δ/p_1 up to 0.10. However, for exceptionally high pressures such as 1200 or 2000 lb per sq in., where n as determined previously may be as low as 1.22, or for large Δ/p_1 or other unusual cases or for checking the accuracy of formula [3], it is desirable to have a fundamental flow formula, and this is next deduced, based on values of volume to be found for each point from steam tables such as Keenan's. As already remarked, we cannot employ any of the usual Mollier diagrams, for small values Δ/p_1.

The area of the pressure-volume diagram, Fig. 16, is obtained by assuming that the isentropic curve between known values of v_1 and v_2 is practically a curve $pv^n = c$, where n is such an exponent (never actually computed) as produces in any given case a curve corresponding to the given volumes. This method makes the assumption that the pressure-volume area under a curve $pv^n = c$ passing through the given points is practically the same as that under the actual isentropic curve. The legitimacy of this assumption has been demonstrated by computation of actual values of n from isentropic volumes found from values taken from Keenan's Steam Tables, for a number of pressure drops from a given initial condition. The value of n turned out to be the same for all points along a given isentropic.

In the use of the exact formula, the quantities found by graphical interpolation from the steam tables, as explained later, are not actually volumes, but values of p_1v_1 and p_2v_2, because these have the most gradual change. These are inserted in the final formula, the deduction of which is given below,

$$w = \frac{1890\,cD^2\,[1 + 2\alpha(t_1 - t_s)]\,\sqrt{p_2^2(p_1v_1 - p_2v_2)}}{p_2v_2\,\sqrt{1 - (D/D_1)^4\,(v_1/v_2)^2}} \times \sqrt{\frac{\log p_1 - \log p_2}{\log p_1v_1 - \log p_2v_2}} \quad \ldots\ldots [5]$$

Graphical Determination of "pv" Values. From the given values of v in steam tables such as Keenan's for various even pressures and temperatures, there are computed and plotted, values of pv against values of temperature t. Just as described for Fig. 15 in a preceding paragraph entitled "Empirical Determination of n" the value of p_1v_1 is found by interpolation. We next plot values of entropy s given in the steam tables against values of t for the same even pressures and for the same range of temperature. It may be necessary to cross-plot at the initial t_1 values of s against the even values of p to give at p_1 the exact initial s_1, or we may interpolate at p_1 between the curves to get s_1.

We next plot values of pv for values of v in the tables against s for even pressures on either side of the actual final pressure p_2, for a range of values of entropy s on either side of the initial s_1. By interpolating or cross-plotting at the initial s_1 between the curves of the values of pv against the even values of p, we find for p_2 the exact final value of p_2v_2. The resulting values p_1v_1 and p_2v_2 are inserted in [5]. This method is somewhat laborious, but very easy to execute, and yields good values of the two pv's.

Deduction of Exact Formula. Saint Venant's formula for flow of a fluid following the law pv^n = const. has often been deduced. For fluids other than a perfect gas (that is, pv not RT) the formula comes out

$$w = \frac{3600\pi\,D^2\,\sqrt{2g}}{48\,\sqrt{1 - (V_1/V)^2}\,\sqrt{1 - 1/n}}\,\sqrt{\frac{p_1}{v_1}} \times \sqrt{\left(\frac{p_2}{p_1}\right)^{2/n} - \left(\frac{p_2}{p_1}\right)^{1+1/n}} \quad \ldots\ldots [6]$$

In the usual deduction, n is a given exponent, and values of v are to be obtained from it. We here reverse the process, and suppose that we know v_2 and that n is that exponent which exactly fits with it in any given case, whatever it may be. We do not assume that n is the same for various isentropics but only that it has a constant value along any one isentropic. We never need to find this value of n, however. We next proceed to transform [6] so as to express it directly in terms of v_2. However, the numerical values are most easily found as values of p_1v_1 and p_2v_2, so that we use these terms. Since $p_1v_1^n = p_2v_2^n$,

$$\frac{p_2}{p_1} = \left(\frac{v_1}{v_2}\right)^n$$

From this it follows that

$$\left(\frac{p_2}{p_1}\right)^{2/n} = \left(\frac{p_2}{p_1}\right)^2 \left(\frac{p_1v_1}{p_2v_2}\right)^2$$

and

$$\left(\frac{p_2}{p_1}\right)^{1+1/n} = \left(\frac{p_2}{p_1}\right)^2 \frac{p_1v_1}{p_2v_2}$$

These relations make it possible to reduce the radical in [6] to the form given in [5].

By taking logarithms of $p_1v_1^n = p_2v_2^n$,

$$n = \frac{\log p_1 - \log p_2}{\log v_2 - \log v_1}$$

By further algebraic procedure we can express $\sqrt{1 - 1/n}$ in [6]. Since the flow is the same in the jet and the approach pipe,

$$\frac{V_1}{V} = \left(\frac{D}{D_1}\right)^2 \frac{v_1}{v_2}$$

so that we finally have [5] from [6].

Discussion

JOSEPH H. KEENAN[12] AND SAM P. SOLING.[13] The metering orifice and the metering nozzle will doubtless assume positions of greater importance in precise engineering testing as our ability

[12] Assistant Professor of Mechanical Engineering, Stevens Institute of Technology, Hoboken, N. J. Assoc-Mem. A.S.M.E.

[13] Instructor in Mechanical Engineering, Stevens Institute of Technology, Hoboken, N. J.

to predict their coefficients improves. The paper brings the subject to the attention of power engineers in the operating and designing fields in carefully considered detail. If it serves to concentrate engineering attention on the problems of accurate orifice metering, it will be of great service.

At Stevens Institute of Technology we have undertaken the measurement of the difference in pressure between the throat of a nozzle and the exhaust space following it and the determination of discharge coefficients using air, water, and steam as the flowing fluids. The capacity of our air-flow apparatus limited us to a throat diameter of 0.6 in.

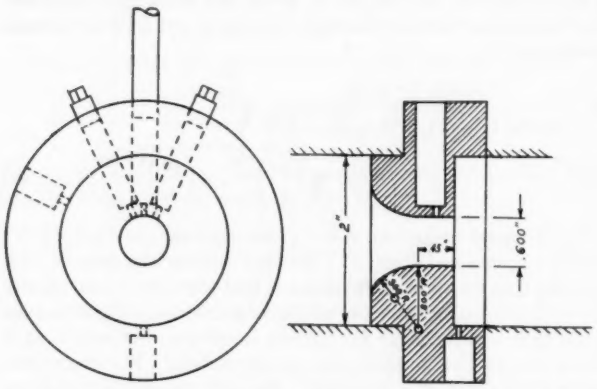

FIG. 17 NOZZLE USED IN STEVENS INSTITUTE OF TECHNOLOGY TESTS

The nozzle walls (Fig. 17) were designed in accordance with the authors' recommendations. It was impracticable, however, to use throat sampling holes as large as $^1/_8$ in., as the authors recommended, because of the small radius of the throat-wall surface. Three $^1/_{16}$-in. throat holes connected in parallel provided the throat pressure to the manometer. These holes were only $^3/_{16}$ in. from the nozzle exit instead of the minimum $^3/_8$ in. recommended, because the entire throat length was less than $^1/_2$ in.

We recognized that these small dimensions would increase the difficulties involved in accurate measurement, but adherence to the minimum dimensions recommended would have forced the nozzle design so far from geometric similarity with those of the authors as to invalidate comparison.

Care was taken to see that the edges of the sampling holes were smooth without excessive rounding. The depth of the $^1/_{16}$-in. drilling was slightly more than $^5/_{32}$ in.

The nozzle was machined out of a solid piece of brass, constituting a flange which could be inserted between standard 2-in. pipe flanges. The exit face of the nozzle was recessed into this flange, giving a short machined length which was continuous with the exit piping when in the operating position. Two pipe taps, each $^1/_{16}$ in. in diameter, opened into the space immediately following the exit face. These were used singly until it was established that no appreciable difference could be found between their pressures, after which they were used in parallel.

This type of pipe tap differs from those shown by the authors, who recommend a pipe-tap set a little upstream from the nozzle exit—an arrangement which is possible only when the nozzle projects into the exit pipe.

The approach pipe in all tests was free from bends or valves for a distance of at least 15 diam. The initial pressure tap was 0.27 in. in diameter and opened into the approach pipe 1 in. before the nozzle entrance in the case of water and 1.6 in. before the nozzle in the case of air and steam.

Pressures were measured with water columns or mercury columns, the drop across the nozzle never giving less than a 3-in. reading on the differential manometer. In the case of water flow, pressures were transmitted to the manometer through water-filled lines fitted with air traps. The steam-test pressure lines were arranged much as shown by the authors.

The results of the tests on the difference between the pressures in the throat and in the exit pipe are shown in Fig. 18. The water and air tests and one steam test appear to scatter about a straight line with about a 3 per cent slope when plotted against the pressure drop across the nozzle. The other three steam tests indicate a higher slope, which was doubtless caused by the accumulation of solid matter from the steam on the nozzle wall. When the nozzle was removed from the steam line, it was found that the brass surfaces had been streaked and discolored by deposited material. The thickness of the deposit was too small to affect measurably the throat area, but probably large enough to alter the stream flow immediately around the throat tap holes.

A similar difficulty but an opposite effect was encountered in the air tests. In the course of several tests it was noted that the difference between throat and pipe-tap pressures, which was being measured directly, was decreasing. The cause of the change was found to be a thin film of compressor oil which was deposited on the nozzle wall from the air stream. Cleaning the orifice with carbon tetrachloride between tests brought consis-

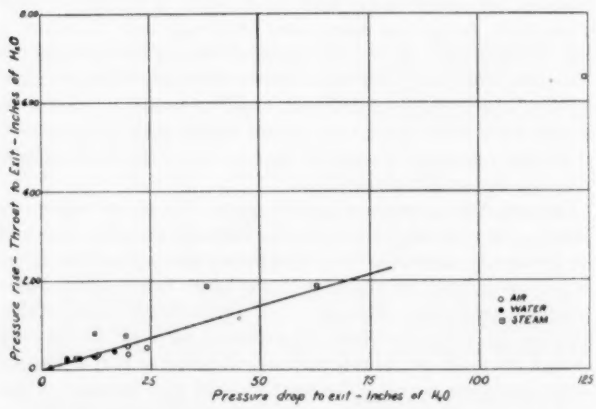

FIG. 18 DIFFERENCE BETWEEN THROAT-TAP AND PIPE-TAP PRESSURES

(The line represents a slope of 2.85 per cent. The high values from the steam tests are probably caused by a deposit of solid matter on the nozzle walls.)

tent results. The least difficulty was encountered in the water tests, during which no material was deposited on the nozzle walls.

Doubtless the difficulties involved in obtaining consistent throat-pressure measurements would have been less pronounced had the dimensions of our orifice and sampling holes been considerably larger. But even in the larger sizes these problems would still be present, though in lesser degree, and it is extremely doubtful whether throat-tap measurements have advantages that justify the difficulties they introduce. It is true that throat taps give a coefficient of discharge fairly near to unity. But the actual magnitude of that coefficient must be obtained from calibration of the orifice in question or of similar orifices regardless of where the low-side pressure is measured.

The statement that the coefficient determined from throat-tap measurements is the same as that of a nozzle freely discharging into the atmosphere or other large region is certainly not true. The jet issuing from the nozzle entrains fluid. That fluid must flow inward from the distant undisturbed atmosphere to the boundaries of the stream. A pressure gradient must exist in the direction of flow of the entrained fluid which causes the pressure surrounding the jet to be lower than that of the undisturbed

atmosphere. It is this pressure immediately surrounding the jet that determines the throat pressure.

Though our nozzle did not discharge into an indefinitely large atmosphere, the ratio of pipe area to nozzle area, 11 to 1, was large enough to approach that condition. Further, the corner position of our pipe tap insures a pressure approximating that of an undisturbed atmosphere. In every case we found the throat pressure lower than the pressure in the exit space. In the more reliable measurements the difference averaged 2.85 per cent of the pressure drop across the orifice, which gives a coefficient from throat pressure approximately $1^1/_2$ per cent lower than the coefficient from exit-space pressure.

Further evidence concerning the direction of this pressure differential is found in the steam-flow test of a freely discharging rounded-entrance nozzle made by Warren and Keenan.[14] Fig. 15 of that paper shows the flow coefficient based on the Marks and Davis steam tables to be about 101.5 per cent at low velocities. Beyond the critical-pressure ratio, where the pressure in the throat assumes the value used in computing the theoretical, the coefficient drops to 99.25 per cent. Thus it is reasonable to assume that the difference between the 99.25 per cent value calculated from the known throat pressure and the 101.5 per cent calculated from measured exhaust-chamber pressure is a measure of the difference between throat and exhaust-chamber pressures. The 2.25 per cent difference corresponds to a throat pressure which is lower than the exhaust-chamber pressure by 4.5 per cent of the pressure drop across the nozzle. The same tests recalculated using the Keenan tables give 101 per cent at low velocities and 99.2 per cent beyond the critical, a difference of 1.8 per cent in coefficient which corresponds to a throat pressure which is lower than the exhaust-chamber pressure by 3.6 per cent of the overall pressure drop. This is a very satisfactory agreement with our measured value of 2.85 per cent.

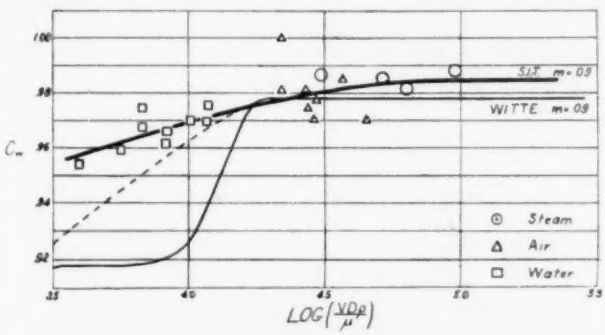

FIG. 19 DISCHARGE COEFFICIENTS FROM S. I. T. COMPARED WITH I.G. NOZZLE TESTS

(The pipe diameter is used in computing Reynolds' number. Coefficients are based on pipe-tap measurements. The dash line bridges over the step in Witte's results.)

[14] "A Machine for Testing Steam-Turbine Nozzles by the Reaction Method," by G. B. Warren and J. H. Keenan, Trans. A.S.M.E., vol. 48 (1926), p. 33.

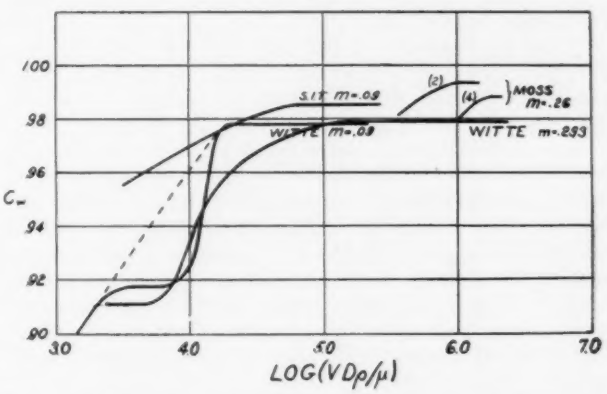

FIG. 20 DISCHARGE COEFFICIENTS COMPARED ON REYNOLDS' NUMBER BASIS

(m = nozzle area/pipe area. Numbers on the Moss and Johnson curves represent the curve numbers in the paper.)

A pipe-tap measurement made in a recessed region upstream from the nozzle exit might give, as the authors claim, a pressure lower than the throat pressure. If so, it is doubtless because of high-velocity local eddies in the constricted space between the nozzle and the pipe.

There is of course no one right place to measure the low pressure in a nozzle test. Since the coefficient used must be determined by calibration in any case, reproducibility of result is the only requirement. Consequently, pipe-tap measurements, which are in general more reproducible with ordinary care, are preferable to throat-tap measurements. It is highly desirable, nevertheless, to standardize the method of measuring low-side pressure in order to facilitate the correlation of results obtained by various experimenters. Only after correlation of comparable experimental results from many sources shall we be able to predict with confidence and with precision the discharge coefficient of a nozzle in any specific case.

Dimensional reasoning indicates that for geometrically similar nozzles in geometrically similar piping systems the discharge coefficient is a function of Reynolds' number and the ratio of nozzle area to pipe area:

$$c_w = f(VD\rho/\mu, m)$$

The validity of the Reynolds number as a criterion has been experimentally verified for a given nozzle in a given pipe by the experiments of Witte. In an extensive series of measurements with water, oil, and steam sponsored by the I.G. chemical industries, Witte[15] showed that the coefficient of discharge of any one nozzle or orifice in any one pipe system was a unique function of Reynolds' number regardless of the fluid used. In the case of the rounded entrance nozzle, the coefficient of discharge remains constant for all Reynolds numbers higher than about 10^5. Be-

[15] Witte, *Z.V.D.I.*, vol. 72 (1928), pp. 1493–1502.

iow that value the coefficient decreases gradually as Reynolds' number is reduced.

If the pressure drop across a nozzle is large enough to cause a marked change in the fluid density during the expansion, then it can be shown dimensionally that a compressibility criterion must be added to Reynolds' number and area ratio in the expression for discharge coefficient. A pressure ratio, final pressure to initial pressure or pressure drop to initial pressure, is usually used as the compressibility criterion. Witte's tests, which covered pressure drops in steam flow up to about 5 per cent of the initial pressure, showed the coefficient to be independent of pressure ratio and consistently dependent on Reynolds' number.

At Stevens Institute of Technology we have obtained discharge coefficients (Fig. 19) using air, water, and steam over a wide range of Reynolds' numbers. Initial conditions and pressure ratios are shown in Table 1. The steam and water flows were determined by weighing. The air flow was measured by determining the course of pressure and temperature with time in a supply tank of known volume. Three temperatures measured at different heights above the tank bottom were averaged to obtain the temperature of the air remaining in the supply tank at any instant. The pressure was held constant ahead of the orifice as the pressure dropped in the tank. The slope of the ratio p/T against time determined the rate of flow. Uncertainties in instantaneous tank temperatures were caused by radiation to the thermocouples from the tank walls during the test. Steps have been taken to eliminate this difficulty and to reduce the spread of the test results.

The points plotted in Fig. 19 show, as do Witte's tests, a good correlation against Reynolds' number, but no consistent trend against pressure ratio. Witte's curve for the same area ratio is compared in the figure with the values from Stevens Institute. The agreement in maximum value (within $^3/_4$ per cent) is fortuitous because the two orifices are not geometrically similar; the I.G. orifice has a smaller entrance radius. The two curves begin their decline at approximately the same Reynolds number, though Witte's curve falls off much more steeply, levels off for a space, and then continues downward. Similar steps appear in Witte's other curves in unsystematic fashion, representing, perhaps, a peculiarity of a given set-up which could hardly be reproduced even in a close copy of it. The dash line bridging the step is doubtless more representative of the general case.

In Fig. 4 the curves from Witte, S. I. T., and Moss and Johnson are shown plotted against Reynolds' number. The Moss and Johnson data are inconsistent with the other two sources in two ways: First, they show variations in coefficient with pressure drop in a region where the other experimenters have found all variation to have ceased; second, they show two separate curves for the same nozzle and pipe combination when operated with steam at two different initial pressures. Our own tests with different fluids and Witte's tests covering a wider range of steam pressures than Moss and Johnson's both show the discharge coefficient to be a unique function of Reynolds' number. Change in pressure, temperature, density, viscosity, etc. caused no departure from the single curve which represents all tests when they are plotted against Reynolds' number.

The authors express the results of all their tests on several nozzles at various pressures (curve 3, Fig. 10) as a single function of pressure ratio. This is in direct contradiction to dimensional reasoning and to recent experimental studies of nozzle coefficients. The agreement shown in Figs. 10 and 11 in the droop in coefficient at low-pressure drop is more probably an indication of systematic error than an indication of the influence of compressibility.

The test data from Stevens Institute should be considered as tentative only. Since the work has been undertaken only recently, there are many opportunities available for improving test equipment and technique. We hope to carry out a further study of the variation of discharge coefficient with Reynolds' number, with area ratio, and with pressure ratio, concentrating for the present on the type of nozzle recommended by the authors.

R. E. Sprenkle.[16] Two nozzle shapes or designs appear in Fig. 1, also in Figs. 8 and 9. The first of these designs in Fig. 1 is of the shaped or flared type, with the outlet connection placed into the wall of the pipe back of the nozzle throat. The second design is formed of a solid block of metal and has the outlet connection placed into the inner throat of the nozzle. Since both of these designs are recommended, the writer presents comparative data showing the relation between these two designs in terms of coefficient of discharge, ability to detect disturbances in the flow, as well as stability in performance. It must be remembered that there are hundreds of nozzles in commercial use today of the flared type using the outlet connection made into the pipe wall back of the nozzle throat, as shown in the upper portion of Fig. 1, whereas there are but comparatively few of the solid-nozzle shapes using the throat connections, in either commercial or testing use.

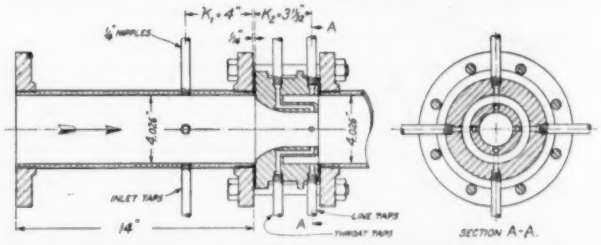

Fig. 21 Special Bailey Test Nozzle

In order to make such comparison tests between the two different designs of nozzles, the Bailey Meter Company made up a special 4-in. by 2-in. test nozzle, as shown in Fig. 21. This nozzle contained the basic characteristics of both designs of nozzles, in that it possessed not only connections going through the throat of the nozzle, but also connections which opened out into the annular space back of the nozzle throat. These latter connections simulated pipe taps precisely, inasmuch as the larger diameter of this annular space corresponded to the inside pipe diameter, whereas the smaller diameter of the annular space corresponded to the normal outside throat diameter. The only deviation in the construction of this special nozzle from the throat-tap kind of nozzle, as shown in the lower part of Fig. 1, is that the throat connections changed direction and ran through the wall of the nozzle instead of straight into the throat as recommended. Four throat and four pipe connections were used, each of these being at 90 deg with each other. The purpose was to detect any disturbances around the inner pipe surface which might be created by improper piping conditions on the inlet side of the nozzle.

In making up the installation of this special nozzle, a short section of 4-in. bored brass pipe was placed immediately in front of the nozzle, this section having a diameter of 4.026 in. Into this pipe section at a distance of one pipe diameter preceding the outlet flange were placed four inlet static-pressure connections, 90 deg apart. The nozzle and this inlet section were then so connected that each inlet static-pressure connection lined up with one throat and with one pipe connection. To each pressure connection was connected a water manometer open at the top

By this hook-up it was possible to take simultaneous readings

[16] Mechanical Engineer, Bailey Meter Company, Cleveland, Ohio. Assoc-Mem. A.S.M.E.

of all the static pressures, not only on the inlet side of the nozzle, but on the outlet side, as measured both along the pipe wall and in the throat surface. Thus it was possible to obtain a direct comparison not only of the coefficients of discharge, but also of the ability of each set of throat and pipe connections to detect disturbances in flow through the nozzle.

All tests made on this nozzle in the company laboratory were run with water. This special nozzle and the short inlet brass section were installed initially as shown in Fig. 22, piping arrangement No. 1. For subsequent tests to determine the relative effect of disturbances on the two kinds of outlet pressure connections, the piping was arranged as shown in Fig. 22, piping arrangement No. 2.

General Electric engineers were invited to witness the tests, and Mr. Johnson responded, and helped to collect most of the data taken in these tests.

Fig. 23 shows the coefficients of discharge obtained on this special nozzle, using both sets of outlet connections. The lower and solid group of lines show the coefficients obtained from the pipe connections, whereas the upper and broken lines indicate

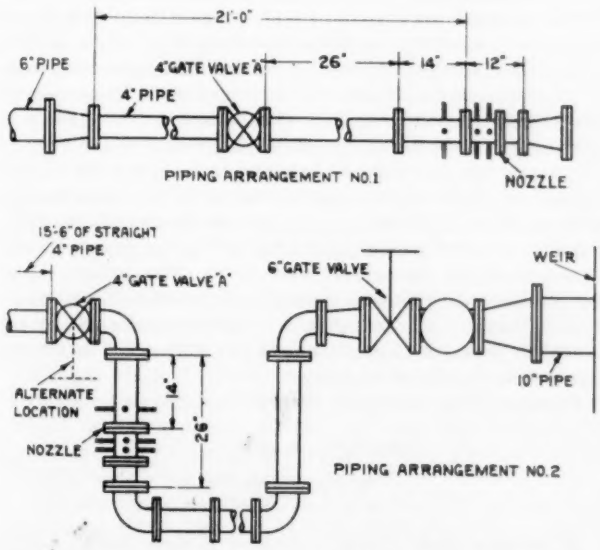

Fig. 22 Piping for Tests on Bailey and G.E. Nozzles (Using both throat and line taps.)

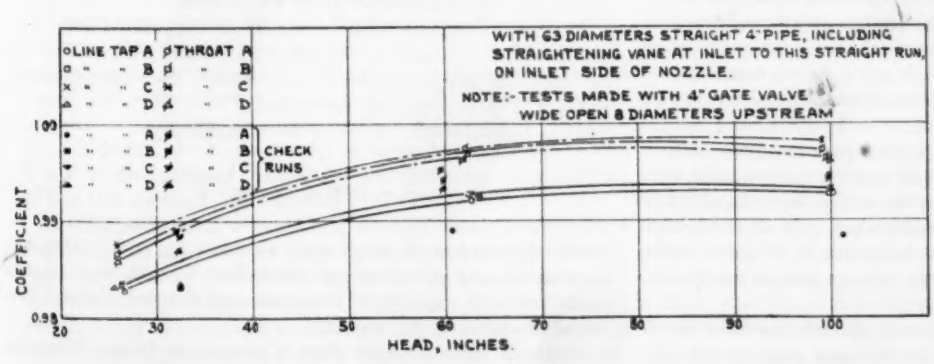

Fig. 23

those obtained from the throat connections. By reference to Fig. 10 in the paper, it will be noticed that the coefficients obtained from the throat connections checked very closely those obtained in the Lynn tests on steam. These data were obtained using piping arrangement No. 1.

Fig. 24 shows the comparative results obtained from the throat and the pipe connections when the special nozzle was installed in piping arrangement No. 2 with the gate valve wide open. It will be noticed that these coefficients check closely those shown in Fig. 23, thus indicating that there was no disturbance produced by this particular piping arrangement.

Again using piping arrangement No. 2, but with the gate valve throttled so that it was only two turns off the seat, the

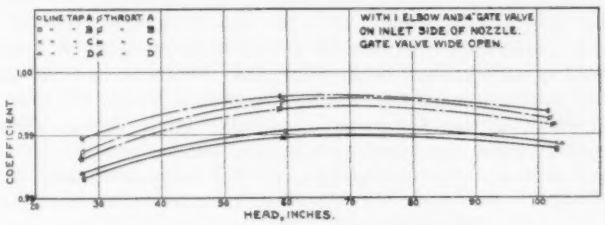

Fig. 24

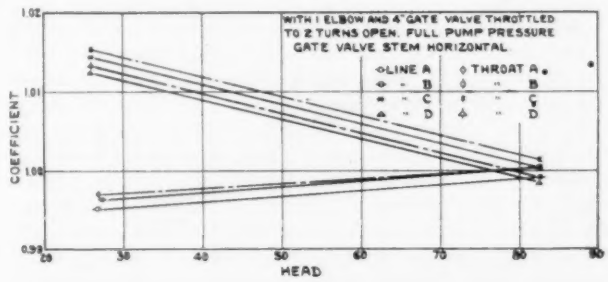

Fig. 25

data as shown in the curve of Fig. 25 was next obtained. It will be noticed that the coefficients of both kinds of outlet connections increased considerably, thus indicating that considerable swirl or disturbance was present. It will be further noticed, however, that there was no appreciable increase in spread of coefficients between either the four-throat or the four-line connections. In this curve as well as in the two previous ones, the upper set of curves, or the broken lines, show the throat-connection results, whereas the lower curves. or the solid lines, show the pipe-connection results.

Mr. Johnson brought with him another special nozzle which had been made in Schenectady, of the same size and general characteristics as the one which we had made up, with exception that the pipe-connection design of the nozzle was omitted. This nozzle was so placed in the set-up that simultaneous readings could also be taken, not only of the differential pressures as measured by the pipe connections, but also by the throat connections, so as to obtain a direct comparison between these two kinds of outlet connections. The results obtained from this nozzle indicated approximately the same differential-pressure variation between the throat connections and the pipe connections as was obtained from the special Bailey nozzle.

In all three of the curves shown it will be noticed that there is a slightly greater spread between the four throat-connection

readings than between the four pipe-connection readings. This is true regardless of whether there is any disturbance in the flow, as is evidenced by the fact that there is approximately the same spread between the throat connections in the case of the installation in piping arrangement No. 1 as in piping arrangement No. 2 with the gate valve throttled, the latter arrangement being that which produced the marked disturbance, as evidenced by the change in coefficients. While this spread between the four throat connections is small, in magnitude, we were still unable to reconcile these results, particularly in the case of piping arrangement No. 1, where we were sure there was no disturbance, until we rotated the nozzle axially in the set-up. We found by so doing that the connections which were giving the highest static readings in the initial position gave the same highest static readings when moved around to positions of 90 deg and 180 deg from their original location. This demonstrated the fact conclusively that the

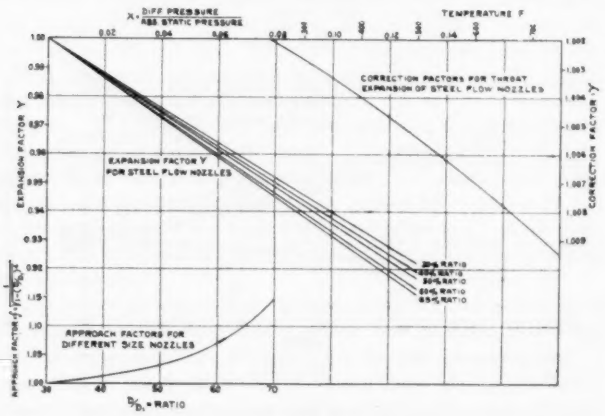

FIG. 26

reason for this spread in coefficients was due not to any disturbances in the pipe, but to the construction of the individual pressure connections into the throat. That is, the edge condition of the throat holes was found not to be exactly the same in all four cases. This meant that the differential as measured between one inlet connection and its corresponding throat connection would not be quite the same as the differential measured between any other inlet connection and its corresponding throat connection. Considerable time was spent in an effort to work down the finish of the openings into the throat, but it was found that it was impossible to get quite as close an agreement between the four different throat connections as between the line connections, even after the nozzle throat had been ground out very carefully and the edges of the throat pressure connections dressed down with crocus cloth and a countersink tool. On the other hand, no difficulty at all was experienced with the pipe connections back of the throat of the nozzle. These four pipe-connection holes were not touched from the beginning to the end of the tests, and thus was demonstrated their marked ability not only to check each other, but also their freedom from fussy details of construction.

As a result of this series of tests, certain definite conclusions can be drawn, as follows:

1 Nozzle-outlet connections placed directly into the throat gave a slightly higher coefficient of discharge than do the pipe connections placed back of the nozzle throat, but that both kinds of outlet pressure connections repeat very well and can be used, therefore, for obtaining a reliable measurement of the differential across the flow nozzle.

2 Pipe connections placed back of the nozzle throat into the pipe wall are just as effective in detecting swirls or other disturbances created by various arrangements of piping set-up on the inlet side as are the connections made into the throat of the nozzle.

3 Throat connections have been found considerably more sensitive to any imperfections of manufacture than pipe connections. This is due to the condition of the edge of the pressure hole into the throat, as the condition of this hole must be precisely the same in every case or the static pressures as measured by the different throat connections will be different. Therefore, great care must be taken in the manufacture of nozzles having throat connections so as to be sure the hole-edge conditions are as uniform as it is possible to make them. Even with this close attention, there is apt to be somewhat more spread or difference between the various throat connections placed circumferentially around the pipe than between the pipe connections.

4 A 50 per cent ratio nozzle is not very susceptible to irregularities in flow conditions except under very adverse conditions. The throttling of a gate valve in the straight horizontal run of pipe preceding it seems to have very little effect on accuracy. In fact, only when in combination with an elbow in such a way that the flow is pushed out to the outer edge of the pipe wall and must then travel through a bend, thus producing a swirl or other disturbance, will adverse calibration be secured.

The formulas given in this paper, while entirely correct, are somewhat difficult in application. They can all be greatly simplified by using the term Y as the expansion factor, the value of which can be found from the curve in Fig. 26 for any set of conditions. As will be noticed, the abscissas on the upper part of this curve are ratios of the differential pressure to the absolute inlet static pressure, with the ordinates at the upper left the corresponding values of the expansion factor Y for steam flow for different ratios of D/D_1, as shown by the diagonal lines. This graphic method of measuring in terms of flow the change of state of steam checks the method used by Dr. Moss within 0.1 to 0.2 per cent, and therefore is amply accurate for all test conditions. Further, it is the scheme as now recommended by the A.S.M.E. Research Committee on Fluid Meters for calculating steam flows through flow nozzles.

Equation [5] of this paper would thus resolve to

$$w = \frac{1890\ cD^2\ (1 + 20\ (t_1 - t_s))\sqrt{Y}}{\sqrt{1 - (D/D_1)^4}\sqrt{v_1}} \quad \ldots\ldots\ldots [7]$$

If we now allow $\frac{1}{\sqrt{1-(D/D_1)^4}} = f$, these values can be obtained from the lower left-hand part of Fig. 26, in which the values of f for each ratio of D/D_1 are plotted.

Further, we can plot values of the throat-expansion factor $(1 + 20\ (t_1 - t_s))$, as shown in the lower right-hand part of Fig. 26, for different temperatures of the steam. The corresponding value of $[1 + (t_1 - t_s)]$ we have called y.

Thus Equation [7] can be further simplified to

$$w = 1890\ cf\ D^2 y \sqrt{\frac{\Delta}{v_1}}\ Y$$

which allows of much more rapid calculations, and further can be used for any calculation of steam flow through steel nozzles regardless of the quality of the steam and the size of the differential produced by the nozzle.

Professor Keenan's tests show a reversal as to the difference between the pipe-tap and the throat-tap coefficients shown by data of this paper and by our own data. The reason for this discrepancy apparently is due to the fact that the throat connection was taken beyond the end of the throat section of the nozzle and in a region where there were apt to be swirls or other disturbances. We have found it necessary to place the outlet connection to any flow nozzle immediately back of the straight

throat section of the nozzle in such a position that no part of the pressure opening projects beyond the edge of the nozzle throat end.

Professor Keenan's graph plots coefficients for different pipe size flow nozzles on the basis of Reynolds' number, and by so doing he finds some discrepancies in the results. Reynolds' number alone is not the proper medium for expressing flow-nozzle or orifice coefficients on the basis of transferring data obtained from one pipe size to another without the use of some auxiliary correction factors to compensate for the pipe-size effect. The necessity of this has been proved by the various types of work which we have done, not only in Cleveland, but at Ohio State University. However, when it comes to the transfer of coefficients from one fluid to another in the same size pipe and using the same primary device, then Reynolds' number does have a decided field of usefulness. In other words, in attempting to obtain steam-flow coefficients from water-flow test data where there is such a large change in viscosity between the two fluids, there must be some correction made to compensate for this factor. In the metering of vapor flow, the differential produced for the lowest rate of flow or Reynolds' number is equivalent to the largest differential head equivalent to liquid-flow metering. The proper coefficient, therefore, to use for steam flow is that which is obtained from the highest differential pressure across the primary when metering water flow. Were coefficients for these primary devices unchangeable with the rate of flow or with Reynolds' number, there would be no reason for this change in transfer, but inasmuch as there is a decided variation in coefficient with head or with Reynolds' number, readjustment must be made in order to obtain the most correct analysis.

G. B. Warren.[17] The authors have, together with the research work and experience of the last few years of the manufacturers of flow meters, obtained sufficient data and developed a technique which should make the flow nozzle, when used with sufficient precautions, a precision instrument of high enough accuracy to permit making turbine tests upon which reliance can be placed. This procedure should not be used to supplant weighed tests when such can be obtained.

There are some aspects of the testing of steam turbines which this paper did not aim to cover and which should be brought to attention.

In connection with large turbines, we have for at least ten years been conscious of the importance of having available, to facilitate proper turbine design, a large body of tests under widely varying conditions of turbines of the most modern design. We have of course carried out extensive research relating to the detail design and performance of the parts of turbines, but after all, the criterion of the value of a design is how it performs in the customer's plant. Such test results on large turbines must be obtained in the customer's plant, as no manufacturer has facilities to test this economy in his factory.

It is necessary that tests made in the field be not only accurate and complete, in covering a wide variety of operating conditions, but that searching analysis determine the meaning of the results in terms of the turbine design. The results must be studied over a period of years and a running study must be made of the relationship of the results on each machine with the results obtained in preceding tests. This we have been doing, and the results so obtained have been embodied in the underlying knowledge upon which turbine design is based.

As to the smaller turbines, prior to the development of this flow-nozzle method of testing, the only accurate system involved the use of weighed flows. On non-condensing and extraction machines this either meant that no tests could be obtained or that expensive and wasteful tests would have to be made in the builder's factory. The short time required for shipment of such smaller machines, together with the highly competitive condition in the market, precluded doing this on more than a few turbines. Further, most of these smaller turbines are in use in industrial applications or small power plants where their owners have rightfully considered that the cost of testing equipment was not a charge which they should be asked to bear, and so such equipment has not been installed. The result has been that manufacturers of small turbines have not been able to obtain the assistance from test results in customers' plants that the manufacturers of large turbines have been able to obtain. It is only fair to assume that the design of the smaller machines has inevitably suffered as compared to what it might have been had ample test information been available, excepting as they have been able to profit by the results of tests on large turbines in the field and tests on small machines in the factory, where these results have been available.

In connection with the use of flow nozzles for testing turbines, the writer would point out the results of certain work which we have done in connection with the testing of larger machines. A few years ago it became quite apparent that in the older stations the condensate-weighing apparatus would not be sufficient to test the larger machines going into these stations and that the pressure for economy in first cost was forcing the builders of new stations to eliminate the installation in many cases of testing equipment. We turbine manufacturers felt rather good about this in many respects, inasmuch as it reflected a changed attitude on the part of our customers who were beginning to have sufficient confidence in our meeting our guarantees so that they could eliminate the making of accurate tests. It is quite a contrast to the European situation, where every customer assumes that the machine has failed to meet its guarantee until the manufacturer proves otherwise. On the other hand, the situation had certain dangers for us in that it meant that, unless some action was taken on our part, we would not be able to get a sufficient body of test information on the large, modern machines. Accordingly we developed a system of flow-nozzle measurement which we could install in the condensate line following the condensate pump on such installations. The pressure differences were measured by a combination of water and mercury U-tubes, and a very careful calibration over a wide range of flows with seven different sizes of nozzles was undertaken with the help of Professor Pardoe at the University of Pennsylvania. These tests and the subsequent experience which we obtained with the use of these instruments and that which was recently obtained at the Hudson Avenue Station on one of these flow nozzles by the Brooklyn Edison Company convinced us that such a system of measurement could be made, and if used with the proper precautions could obtain very accurate results. During the last four years we have tested about ten turbines with this equipment.

When we plotted the flow coefficient of these nozzles, ranging from $1^1/_4$ to 5 in. in diameter against the Reynolds number, we found that the flow coefficient of a group of geometrically similar nozzles is a function only of the Reynolds number. As a result of this we feel quite confident that we can predict the coefficient of nozzles when made geometrically similar to these and used to measure water, to within plus or minus 0.2 per cent. We are, however, still testing any new nozzle either before or after each important test.

The ease and inexpensiveness of making turbine tests should now permit the users of turbines, both large and small, to obtain performance tests on their machines. The results of such tests if made available to the manufacturers should be of material assistance to them in continuing to make progress in turbine

[17] Turbine Engineering Department, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

design, and in addition should serve as a healthy stimulant toward making them continue to live up to guarantees.

FRANCIS HODGKINSON.[18] A reasonably accurate and standardized method of determining a steam quantity by means of flow through an orifice is needed. The Steam Turbine Test Code of The American Society of Mechanical Engineers, as it stands today, discriminates against the determination of steam quantities by orifice-flow measurement, while, on the other hand, the Steam Turbine Rules for Acceptance Tests of the International Electrotechnical Commission permit this determination by this means. The A.S.M.E. code is now undergoing revision, and in the revised code this discrimination will probably have been removed. Of course, there will be appropriate precautions, made mandatory, to secure accuracy, with perhaps some qualifications as to the expected accuracy. Such measurements, however, are not to be confused with those by means of commercial flow meters, and turbine manufacturers have been justified in the past when they have declined to recognize acceptance tests if carried out by any such means.

Steam-quantity measurements by orifice-flow means have made more progress in Europe than in this country. The standardized nozzles of the V.D.I. are commonly employed. It is suspected that this greater progress in Europe is due to the reason pointed out by Mr. Warren, i.e., that in many European countries the burden of proof that the machine under consideration conforms to the contract warranties is on the shoulders of the manufacturer, which is contrary to the principles of common law. In Europe, the manufacturer has to carry out the test with little or no assistance from the purchaser beyond the purchaser exercising vigilance to assure himself that the test results represent the facts. Frequently, the arrangement of the plant is such that a test cannot be carried out by means of the weighing of condensate, except at an inordinate cost. Hence, the great need of the less costly method of means of measurement.

As far as the I.E.C. Rules for Acceptance Tests of Steam Turbines are concerned, while determinations by means of flow measurement are permitted as at present written, they are non-mandatory because a special committee of the International Standards Association has been appointed to study the subject and to formulate standardized nozzles and rules for the carrying out of such measurements. It is expected that the I.E.C. rules will remain non-mandatory until such time as the I.S.A. completes its work, when its reports will be considered, and then the I.E.C. rules will be revised and made mandatory. Beyond doubt, the A.S.M.E. test code is bound to permit steam quantity measurement by some such means as described in the paper.

DAVID J. BLOOMBERG.[19] The paper has properly given detailed treatment to the "test set-up." However, even with a perfect test set-up, there are many chances for slip-ups with respect to obtaining the correct result. In this discussion an attempt will be made to set down the results of our experience in this respect.

In any test system for the determination of a quantity, the difference between the derived test value and the true value is affected by three factors; namely: (1) test setup, (2) test observations, and (3) computation of test results.

While it is possible that differences due to each of the three factors may offset each other, still the width of the band between the true value and the derived test value may be the numerical sum of the individual differences due to all three factors.

It is obvious that for the precision called for in this flow measurement the differences or the errors contributed by each of the three factors should be kept to as low a value as consistent with the time-accuracy characteristic. In the paper the "test set-up" is well taken care of. There is, however, a certain relation between the test set-up and the test observations for precision testing. The test set-up should be planned to permit the test observations to be taken by the observers with the minimum fatigue.

The total time duration and the time interval between observations will depend upon the steadiness of the steam conditions. The greater the time duration and number of observations, the greater the opportunity for the law of averages to balance out observational errors.

Thus while the errors due to the test set-up are fixed, those set up by test observations can be partly controlled by the arrangement of the test instruments and the time duration and number of observations. The statement is often made that the precision of the computation of the test observations need not be any greater than that of the observations themselves. This may be true if we were dealing with a large number of independent tests at the same conditions, or conditions that would lend themselves to graphical presentation permitting an average characteristic curve to be drawn through the points. However, in the case of flow-nozzle tests there usually is only one point, and therefore the width of the band of the deviation of the derived test values from the true values will be that of the arithmetical sum of the mean deviations resulting from the three factors—test setup, observations, and computations.

The magnitude of the error contributed by the flow computation is under more positive control than that of the other two factors, and therefore there is no reason why this should not be kept down to $^1/_{10}$ of 1 per cent.

In our experience we have found it desirable to rearrange Equation [3] so as to permit the use of curves and thus facilitate the flow calculations. The equation as rearranged is:

$$w = \frac{1.664\ cD^2\ [1 + 2\alpha(t_1 - t_s)]}{\sqrt{[1 - (D/D_1)^4 + 1.562\ (D/D_1)^4\ \Delta/p_1]}} \times p_1 \times 1136 \sqrt{\left(\frac{1}{p_1 v_1}\right)} \times \sqrt{\left(1.17\ \frac{p_2}{p_1} - 0.17\right)\left(1 - \frac{p_2}{p_1}\right)}$$

The term $1.664\ D^2\ [(1 + 2\ \alpha(t_1 - t_s)]$ for a given nozzle is plotted against t_1 as abscissa. The value of α varies with different materials.

The term $\sqrt{[1 - (D/D_1)^4 + 1.562\ (D/D_1)^4 \Delta/p_1]}$ is plotted against D/D_1 for different constant values of $\sqrt{(\Delta/p_1)}$.

The value of c, being a function of Δ/p_1, can be incorporated in these curves.

The term $1136\ \sqrt{(1/p_1 v_1)}$ is taken from the steam-flow equation used in our steam-turbine calculations. Mr. E. C. Perry, of the General Electric Company turbine engineering department, first introduced the use of the curves of $1136\sqrt{(1/p_1 v_1)}$ plotted against p_1 for different constant values of initial temperature and superheats. These curves can be plotted on small curve sheets with a fairly open scale, permitting the reading of the values with accuracy well within $^1/_{10}$ of 1 per cent.

The values of the final term $\sqrt{[(1.17\ p_2/p_1 - 0.17)\ (1 - p_2/p_1)]}$ are best presented in form of a table, for even values of Δ/p_1.

The application of the flow nozzle in measuring the inlet flow in connection with turbine efficiency tests has one advantage, which has not been previously stressed. That is, an observational error in the steam temperature will cause comparatively little

[18] Consulting Mechanical Engineer, Westinghouse Electric & Manufacturing Co., South Philadelphia Works, Philadelphia, Pa. Mem. A.S.M.E.

[19] Research Engineer, Turbine Engineering Department, General Electric Company, River Works, West Lynn, Mass. Assoc-Mem. A.S.M.E.

error in the calculated turbine input, since the effect of this temperature error on the derived flow will be to a large extent balanced by the effect of the same temperature error on the available energy used in determining the turbine input. To retain this beneficial feature, the relation of the turbine-inlet temperature to nozzle-inlet temperature should be correctly determined. Our experience has been that with well-lagged pipe between the flow nozzle and the turbine inlet, the heat losses are relatively small and the temperature differences will be that due to steam throttling.

N. E. Funk.[20] It is pleasing to learn that the steam-turbine manufacturers are at last satisfied that it is possible to meter the flow of steam in pipes with sufficient accuracy to be acceptable for turbine tests. For many years the writer has felt that it was desirable to find some substitute for the expensive and clumsy method of determining the condensate from a turbine with weighing or measuring tanks.

In 1920 the Philadelphia Electric Company arranged for metering the condensate on the turbines which were installed in its Delaware station. This was done by inserting a removable section of pipe containing an orifice in the condensate line. This removable piece of line could be inserted in a system of piping containing a V-notch meter in which water was circulated by means of the pump so that the pipe and orifice combined could be accurately tested. Later, in 1925, a similar arrangement was used with the installation of the 60,000-kw turbo-generators at the Richmond station, together with a new V-notch measuring equipment necessary because of the increased amount of flow. The V-notch meters in this installation were accurately calibrated at the University of Pennsylvania. A description of this equipment can be found in the technical publications.[21]

The turbine test results obtained from the use of orifices so calibrated have been extremely satisfactory in determining the initial turbine performance and for the purposes of closely following the economic operation of the stations. Although turbine tests were always made using a special mercury column for accurate measurements, the regular operating procedure is to connect a standard recording flow meter to the calibrated orifices. This combination is sufficiently accurate to permit closely following daily plant performances.

This method of course has left much to be desired because it was only applicable to the measurement of water. It is very gratifying that equipment has been developed to permit the measuring of steam with the accuracy that we have been able to obtain for a number of years in the measurement of water.

Edward C. Perry.[22] It seems worth while to call to the attention of those who may try out this system certain precautions in the set-up and condition of the differential U-tubes (Fig. 7) which, if neglected, may nullify the refinements of theory expressed in the formula and apparatus:

(*a*) The illumination of the U-tube should be carefully studied. It must be adequate. It should be so arranged that no shadows or reflections make it difficult for the operator to take his readings quickly and easily. There must be a good light under the sliders at all positions; hence a movable light is usually desirable. Sometimes this can be supplemented or replaced by a beam reflected from a small mirror in the hand of the operator. Avoid direct light from windows or skylights, which may cause troublesome reflections on the glass in front of the tubes.

(*b*) In addition to good light, it is important to have the brass scale bright, the interior of the box white, and the glass in front clean.

(*c*) The position of the U-tube above the floor should, if possible, be such that the operator can always keep his eyes on a level when taking readings without getting into difficult positions. In the case of large deflections, the operator can sometimes use a small mirror, lining up the slider with the meniscus by means of the reflection. This is usually necessary only on the lower slider, and often helps in checking the upper and lower levels without moving the eyes from one level to the other.

(*d*) The U-tube should of course be placed where there is no hindrance from surrounding objects or from other persons.

S. A. Tucker.[23] The use of the flow nozzle where the fluid to be measured is steam is a problem not met often in central-station testing where the quantities are very large and the condensate is usually available for flow-nozzle or weighed-water measurement. Because of the trend in central-station design toward minimizing interconnections between units, centralized weigh tanks are becoming an increasing burden on the already high cost of acceptance tests.

The cost of revising our weigh-tank equipment was recently emphasized by modifications necessary to permit testing 160,000-kw units. We therefore have recently made two series of tests at Hudson Avenue with the cooperation of the General Electric Company on a flow nozzle of their design similar in shape and characteristics to those described in the paper.

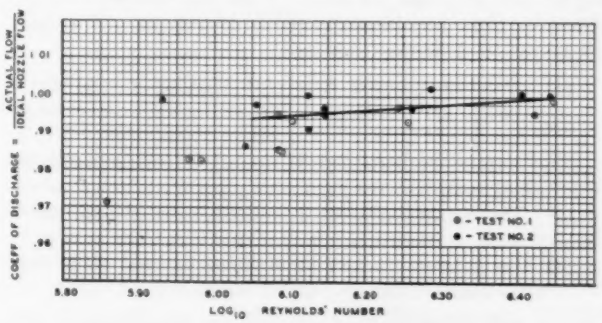

Fig. 27 Calibration of Flow Nozzle, Hudson Avenue Station

A 5-in.-throat-diameter nozzle was installed in the 12-in. condensate return line and calibrated during acceptance tests on two condensers, at which time the condensate was being weighed.

The curve of Fig. 27 shows the results of 20 1-hr test runs plotted against the logarithm of the Reynolds number. Before starting the test it was recognized that two such nozzles would be desirable to cover the range corresponding to the range of test points with relative throat areas in the ratio approximately 2 to 1. The curve, therefore, has been drawn only for the region in which the larger nozzle would be used even though measurements were actually made at the lower flows at small deflections. Full-scale deflection on the manometer was about 30 in. of mercury. Some pulsation of the mercury was observed, but the motion was so slow that fair accuracy of reading was obtained, particularly in the second set of runs, where the frequency of reading was increased from 2 min to 1 min.

These test runs under commonly met service conditions hold

out a hope of better accuracy for nozzle measurement of condensate flow than has heretofore been generally accepted.

E. D. DICKINSON.[24] Engineers have recognized for a number of years the ever-increasing necessity for a simple means of correctly and accurately measuring the steam used by turbines. There are several reasons that have tended to emphasize this necessity:

(1) The necessity for low-cost production to meet present-day competition has emphasized the need of higher efficiency of prime movers, which are an integral part of manufacturing process.

(2) An increase in the proportion of non-condensing and extraction turbines. It is impracticable to test these by condensing and weighing the steam from the exhaust.

(3) The increase in size of the non-condensing and extraction units, which in consequence emphasizes the importance of saving fuel.

The existing commercial situation would be almost ludicrous were it not so serious. Efficiencies are discussed to a fraction of 1 per cent when it is known that in many cases there has been no recognized practicable means for positively determining the efficiency of the turbine after it is built. The number of non-condensing and extraction turbines accurately tested in the field is negligible.

The paper describes the results of many years of research. This work was the natural outcome of the development of the nozzles used in steam turbines. What the authors have described can in no way be considered an instrument. They have endeavored to show the following:

(1) A nozzle inserted in a pipe carrying steam can be used to give readings of flow with a high degree of accuracy
(2) Nozzles proportioned as described will give reliable and consistent readings with pipes of different sizes
(3) The nozzle coefficient is uniform over an appreciable range
(4) Accurate results can be obtained without calibrating the nozzle when using throat taps.

It goes without saying that all necessary care and precaution must be taken in conducting a test to assure accurate results. The system cannot be considered in any way as competing with commercial flowmeters, but rather might be considered as a natural adjunct. It is not the intention that the nozzle would remain in the steam pipe at all times, for the reasons that it should be inspected before and after each test and that the pressure drop would result in considerable loss if used continuously.

While the system has many compensating advantages, it is not adapted to measuring fluctuating flows. The advantages are:

(1) It can be readily installed at relatively small cost
(2) It can be used to measure superheated or dry steam
(3) Test can be run quickly, reducing the cost of testing
(4) Many points can be run on a curve in a relatively short time
(5) All the steam to the turbine is measured. There is no question of loss in drips or drains. No corrections have to be made for condenser leakage.

S. R. BEITLER[25] AND T. C. BARNES.[26] This paper represents a very important step in the right direction, in suggesting the use of a metering device for acceptance tests of steam turbines. Modern metering practice, however, makes use to a great extent of square-edged orifices in measuring flows of all kinds, and these are believed to be as accurate a metering element as any other. In addition, the venturi tube has long been used as a primary element, and the characteristics of it are very well known. Any method adopted for a standard should, then, not be limited to any particular metering device, but should permit the use of any device of sufficient known accuracy.

It has been the writers' experience that the nozzle with low-side pipe taps is the more desirable for general use as it is much less sensitive and easier to construct. Since the throat taps are placed at the point of maximum velocity, they must be so carefully constructed that it is almost beyond the capabilities of the ordinary mechanic. Any good pipe fitter with proper supervision can install the other type, however, without much difficulty.

In the manufacture of any nozzle, care must be taken to see that the throat is round and that the sides of the parallel portion are actually parallel. It is better to have a slight convergence in the section than any divergence whatsoever. In installing the nozzle care must be taken to have the center of the nozzle in the center of the pipe, and the axis of the nozzle must be coincident with the axis of the pipe. This means that the parallel section of the nozzle must be perpendicular to the flange of the nozzle.

J. C. HOBBS.[27] In order to obtain an accurate picture of the results obtained, the writer would ask two questions:

First, if the desired sizes and arrangement for the measurement of any steam flow can be obtained in each practical case, what accuracy in the final results should be expected?

Second, will the results obtained be acceptable on turbine acceptance tests by the General Electric or other turbine companies without allowance for unknown errors? In other words, if the steam-flow meter after applying all coefficients and corrections still shows a difference from the guarantee, will the meter figure be used as a basis for payment of bonus and penalties?

AUTHORS' CLOSURE

The discussion indicates an interest in this proposal for accurate measurement of steam by means of flow nozzles that is very gratifying. There have been brought out many differences of detail with regard to use of flow nozzles, which reflects the present chaotic situation with respect to them, since nearly every person who measures flow uses a different arrangement of nozzle shape and other details. This presentation of so many differences of detail in the discussion further emphasizes the need for standardization of a single definite system which will thereafter be adhered to by all those who desire to use a flow nozzle for precise measurement of flow. There is presented in the paper a single set of details, mostly selected from the diverse systems in use, which the authors believe most satisfactory for a standard system. These are such as to reduce losses and irregularities to a minimum, so as to give a flow which approaches the theoretical as nearly as possible and so that the discharge coefficient to be used with a rational formula is as nearly unity as possible. It is felt that this is safer than the introduction of items used merely for the sake of convenience, which lower the coefficient, even though a calibration is made to allow for them.

The authors reiterate that the paper discusses only the case of flow-measuring apparatus especially installed for an acceptance test or the like, where certainty of accuracy is the primary consideration. Commercial flowmeters are giving excellent satisfaction in a wholly different territory. Commercial flowmeters

must be suitable for permanent and simple installation in the usual commercial pipe line with small pressure drop, must give a direct reading, and must be easy to maintain. They usually depend upon a vendor's guarantee for accuracy. (If a guarantee of a vendor be acceptable, the guarantee of the apparatus tested by the nozzle might as well be accepted at once, which would eliminate the necessity for a test.) None of these considerations can be allowed to influence nozzles to be used for precise measurement with certainty of accuracy, which is the subject of the paper. The authors feel that a test on the basis described in the paper, conducted by experts, furnishes a flow measurement which may be used with complete confidence in investigating the performance of a guarantee, so that the results, no matter what they may be, will be accepted without hesitation and without question of the accuracy of the test. Attempts to measure flow without the precautions cited in the paper have in the past usually resulted, not in any useful information, but only in discussion as to the accuracy of the test.

Fig. 1 shows to scale the particular case where the nozzle diameter is half that of the preceding pipe. In Fig. 1 the pipe diameter referred to is the actual inside diameter and not the nominal diameter. In Fig. 1, with pipe diameter $2D$, the axial distance from the center of the small radius to the intersection of the inlet curve with the inside pipe wall comes out to be $^{15}/_{32}D$. For pipe diameters of $2D$ or more, it is proposed to have this distance establish the inlet face. The small radius will therefore not be continued to tangency. The intersection with the nozzle face at $^{15}/_{32}D$ shall be rounded with a radius of about $D/20$. In this case, the overall length of the nozzle comes out $1^{23}/_{32}D$, or $1^{15}/_{32}D$ plus $^{3}/_{8}$ in. for nozzles with D less than $1^{1}/_{2}$ in.

With pipe diameters between $1^{2}/_{3}D$ and $1^{9}/_{16}D$, the preceding shape does not give sufficient flange face. Then the overall length of the nozzle shall be reduced on the inlet end to make the nozzle inlet diameter (the intersection of the inlet curve with the face of the nozzle) equal to 1.05 times the actual inside pipe diameter.

In recent use of the system of the paper, and in confirmation of statements in the Keenan and Soling discussion, it has been found desirable to have a cleanout immediately following the nozzle, for inspecting it, and for cleaning it if necessary. This cleanout must be designed so as to keep at least four pipe diameters of unchanged pipe section immediately following the nozzle. In pipe sizes of 4 in. or less, a run of 4 diameters followed by a removable elbow or tee is satisfactory. In larger sizes a special pipe or casting is necessary, with a hand hole and cover, such that the inner pipe contour is not altered. A tee with a blank over the side outlet might create a disturbance of the flow.

It is interesting to note from the Keenan and Soling discussion that the Stevens Institute of Technology is investigating this matter of precise flow measurement. However, their nozzle with diameter only 0.6 in. is very much smaller than anything which would occur in usual flow measurement. It is to be hoped that the Stevens work will be continued with larger nozzles and with direct comparison of the exact details proposed in the paper with others which may be thought better. Their $^{1}/_{16}$-in. pressure holes are, as they state, easily affected by dirt deposits or burrs. Their three throat taps were connected together, and were all drilled into a short arc on one side of the nozzle. This is an unusual arrangement.

This discussion rightly states that a discharge coefficient determined from a throat tap is different from that of a nozzle discharging freely into the atmosphere or other large region. However, the difference is of so small a magnitude that the effect on the discharge coefficient is negligible. This fact was the basis of the statement in the paper that the coefficients for the two cases are identical.

The authors have made a number of tests with a nozzle discharging freely into the atmosphere, with measurement with a draft gage of the difference between the static pressure shown by a throat hole and the pressure of the atmosphere, and have found that with properly formed throat holes the difference was so small that it could not be detected with the draft gage which was used.

The fluid entrained by the jet and flowing toward it from a distance is a very gentle breeze, as is known to any one who has been near a jet discharging into the atmosphere. We have had a great deal of experience with a 20-in. nozzle discharging into atmosphere with differential pressures of about 15 lb per sq in. The entrained fluid had a velocity certainly less than that corresponding to a breeze of about 10 mi per hr. Such a breeze would give a pressure gradient of about $^{1}/_{16}$ in. of water, which is certainly insignificant. It is to be noted that there is a very slight pressure drop between the plane of the throat taps and the end of the nozzle, as well as the very slight pressure gradient mentioned between atmosphere at a distance and the region around the jet. Any difference in coefficients between nozzles using throat taps and nozzles discharging into the atmosphere is due to the difference between these two effects, which seems very small indeed.

Contrary to the statements in the discussion, the region into which the Keenan and Soling small nozzle discharged, or the region into which was discharged the nozzle of the Warren and Keenan A.S.M.E. paper to which they refer, certainly was not a large region, and there probably existed in both cases powerful eddies. In the case of the nozzle in the Warren and Keenan A.S.M.E. paper, it is known that there was a great deal of circulation in the chamber, and screens were introduced to eliminate the effect, as shown in Fig. 13 of the Warren and Keenan paper. Furthermore, this nozzle had a comparatively small entrance radius, so that the jet probably did not fill the throat at high velocities. This gives a coefficient which decreases at high velocities, as is shown in Bureau of Standards Research Paper No. 49, Fig. 12, nozzle A-4.

The area ratio of 11 to 1 of the low-pressure pipe and the nozzle of the Keenan and Soling tests corresponds to a diameter ratio of 3.3 to 1, which certainly gives back flow due to entrainment much more vigorous than with a nozzle discharging into an infinitely large region. Furthermore, the Keenan and Soling low-side pipe taps were located in a corner where they undoubtedly received impact from the back flow of the entrained stream. This is in contrast with both the throat taps and pipe taps recommended in the paper for low-side taps, which are located in regions where the flow is parallel to the walls.

This impact effect, due to the particular location of the Keenan and Soling low-side pipe taps in a region certainly not large, was undoubtedly the reason why they gave a pressure higher instead of lower than that of the throat taps.

For the case of a nozzle located in a pipe of ordinary size, it is of course true that the arrangement of the low-side taps is of the utmost importance. After a careful review of all known methods, the authors proposed the two alternate arrangements given in the paper—viz., throat taps, and pipe taps located according to an exact specification slightly upstream from the plane of the nozzle mouth. These are the only places where a true static pressure can be taken—i.e., by a tap located at right angles to the direction of flow. The only objection to the throat taps—i.e., the high velocity of the jet at that point—is easily taken care of by having good pressure holes and a clean nozzle. This arrangement also requires the minimum amount of calibration to permanently establish coefficients which may thereafter be used with confidence with nozzles following the given specifications.

The authors are definitely opposed to any attempt to measure static pressure in a corner or other region of curving flow, such as

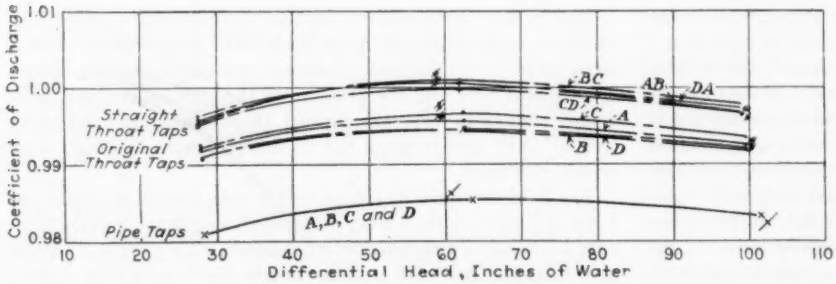

FIG. 28 STRAIGHT THROAT TAPS COMPARED WITH THE THROAT TAPS WITH A RIGHT-ANGLE BEND OF NOZZLE OF FIG. 21

the pipe taps of the Keenan and Soling nozzle. Any pressure so measured is a combination of pressure and velocity effects, and any coefficients based on such pressures have no real meaning, and are also easily affected by inevitable irregularities.

This discussion reiterates the well-known theory that the proper abscissa for plotting of discharge coefficients for nozzles with rounded approach is the Reynolds number. It is not the purpose of the present paper to discuss the pros and cons of the Reynolds number controversy. It is certainly true that no discredit can be cast upon our own tests because of their failure to coincide on a Reynolds number basis with other tests made with wholly different nozzle shapes and pressure-hole arrangements such as the IG nozzle used by Witte. However, Mr. Sprenkle has pointed out that the Reynolds number is not a complete criterion. There have also been a great many other objections to the use of the Reynolds number, previously printed in our own Transactions, such as in the paper by Mr. J. M. Spitzglass, A.S.M.E. Trans., Vol. 52, paper No. HYD-52-7c, and the joint discussion of this paper and papers Nos. 52-7a and 52-7b.

The authors used pressure ratio as the abscissa for discharge coefficient curves merely because it was a convenient way to bring together various tests on a single nozzle with moderately varying pressures and temperatures. In order to bring together tests made on air, steam, water, etc., with a given nozzle, it has also been proposed to use "head" as the discharge coefficient abscissa, which is nearly the same as pressure ratio for a single compressible fluid. This matter of the best abscissa for flow-nozzle discharge coefficient curves certainly needs considerable further investigation.

Mr. Sprenkle gives in Figs. 23, 24, and 25 some comparative, simultaneous readings of throat taps and pipe taps. However, his throat taps, as shown in Fig. 21, had a right-angle bend immediately adjacent to the high-velocity jet. As shown by Professor Allen's classical paper read at the last Annual Meeting ("Piezometer Investigation," Trans. A.S.M.E., paper No. HYD-54-1), a static hole for pressure measurement should be straight and of uniform size for a length from the wall adjacent to the fluid equal to at least two hole diameters. This condition was not satisfied by the throat taps shown in Fig. 21. Fig. 28 shows a third set of comparative readings taken as part of the tests which Mr. Sprenkle cites, but which he does not include in his discussion. The throat taps in this third set of tests satisfied Allen's criterion, and were straight holes of uniform size extending away from the nozzle throat for a distance of several hole diameters. After the tests given in Figs. 23, 24, and 25, posts were inserted in the nozzle of Fig. 21, across the space from nozzle to pipe wall midway between the original short throat taps. There were drilled in these another set of straight throat taps satisfying Allen's criterion. The nozzle throat was then ground and the hole edges dressed. Fig. 28 shows coefficients from simultaneous readings with the three systems of low-side pressure taps. The four upper curves of the figure show the results with the four new straight throat taps. The four middle curves show results with the original short throat taps. Both show the spread which Mr. Sprenkle cites, but this spread has now been reduced to a very small amount by the extra effort to get good holes. The average of the four upper curves, however, is now definitely different from that of the four middle curves, which illustrates the value of Allen's rule. The fact that the discharge coefficient is practically unity shows that the weir used for measuring flow in these tests actually had a calibration coefficient.

The lower curve of the figure is that obtained by Mr. Sprenkle's pipe taps and is appreciably lower than that obtained with proper throat taps, on account of the evacuation and reversed current previously cited. However, the values are lower than those obtained before the insertion of the posts for the straight throat taps. These posts undoubtedly affected the reverse current, the pressure of which is measured by the pipe taps.

Mr. Sprenkle proposes a rearrangement of the terms in the final flow formula to bring it under a general formula for any fluid and any nozzle, including an orifice in a thin plate. Mr. Sprenkle does not give the mathematical basis of the curves he mentions. If, however, these curves are so constructed that they give results identical with the formulas of the paper, there is of course no objection to their use.

FSP-55-11

Stoker Developments at The Detroit Edison Company's Delray Power House No. 3

By PAUL W. THOMPSON[1] and FRED J. CHATEL,[2] DETROIT, MICH.

Experience gained from nearly three years' operation of the large single-ended stokers at Delray has led to developments and improvements in design, the application of which has made them comparable with other types of coal-burning equipment. Improvements have been made with two things in mind—namely, an increase in efficiency of combustion and a reduction of maintenance by decreasing burned stoker parts. All improvements possible, particularly those to improve combustion, have not as yet been completed; however, changes that have been incorporated have materially improved performance. Automatic control of preheated air to the various parts of the fuel bed has been sufficiently developed to establish it as a desirable and valuable aid to combustion, particularly with long stokers burning high-volatile coal. One of the stokers has been operated successfully for a short period with preheated-air temperatures as high as 500 F. Development of a similar air-control system, manually operated, under two boilers in the Beacon Street Heating Plant, handling cold air, has resulted in an increased steaming capacity of 31 per cent and an increase in calculated boiler efficiency of from ½ to 2 per cent. The paper is a description of the Delray installation, but reference is made to the large double-ended stokers, supplied with cold air, and the manually operated metered air control in the Beacon Street Heating Plant.

P. W. Thompson

F. J. Chatel

At the time Delray Power House No. 3 was placed in operation, the latter part of 1929, the five stokers installed were the largest of their type then to have been built. The initial installation consisted of five underfeed stokers, 15 retorts wide and 57 tuyères long. They were rated to burn 34,000 lb of coal per hour with a projected grate area of 611 sq ft when supplied with preheated air at 350 F. Drives were through cog belts from 35 hp d-c motors having a speed adjustment of from 500 to 2000 rpm with drum-type controllers having 21 points of speed control. Each retort of the stoker was equipped with six coal pushers and a movable extension grate. The two-roll clinker grinder was driven by a 5-hp adjustable-speed d-c motor. A cross-section of the boiler unit and the stoker is shown in Fig. 1.

The design of this power station contemplates the ultimate installation of ten boilers to supply steam to six and possibly seven 50,000-kw turbo-generators. The present generating capacity consists of two 50,000-kw units and a 10,000-kw experimental high-temperature unit. A third 50,000-kw unit is now being erected and will be supplied with steam from the present boiler plant.

Selection of Equipment

Fuel-Burning Equipment. The single-ended boilers installed in Delray were a distinct departure from The Detroit Edison Company's present practice. Boilers with double-ended firing have been installed in all the older plants, with the exception of Delray Power House No. 1, which became obsolete several years ago and has been dismantled.

This selection was made to simplify the boiler house arrangement and to economize in building investment rather than because of any dissatisfaction with the double-ended design. With the single-ended boilers arranged in pairs, one coal-conveying system, one row of bunkers, and one firing aisle replaced the three firing aisles, the three rows of bunkers, and the cross-conveyors for coal distribution which would have been necessary with the double-ended type. It was thought that by placing the economizer and air preheater at the back of each boiler, there would be a saving in building height.

These considerations which led to the selection of single-ended boilers indicated a lower first cost. However, a study, made later, on a comparable double-ended boiler plant indicated that such was not the case. The operating convenience of the single-ended design is its only advantage.

The selection of stokers for the initial installation was based on an item which normally would not receive consideration—that of ash disposal. Operating experience with pulverized coal at Trenton Channel and stokers at Marysville had indicated a fairly close comparison between the two methods of firing as to efficiency and ease of operation. Estimates of required investment for the two types of plants indicated total costs so nearly

[1] Chief Engineer of Power Plants, The Detroit Edison Company. Mem. A.S.M.E. Mr. Thompson was graduated in 1910 from Cornell University with the degree of M.E., and for the two years following was an instructor in heat-power engineering at Cornell. In 1913 Mr. Thompson was employed on designing and research engineering by the McIntosh & Seymour Corporation in Auburn, N. Y. Since 1913 he has been connected with The Detroit Edison Company, with the exception of two years' service in the U. S. Army as Major, in charge of inspection of all army ordnance material manufactured in the Cleveland district. Following the armistice he was appointed a member of the Cleveland District Army Ordnance Claims Board. He is the author of a paper on "Tests of a Type-W Sterling Boiler" presented at the Annual Meeting of the A.S.M.E., December, 1922. Mr. Thompson is a member of the A.S.M.E. Critical Pressure Steam Boiler Research Committee.

[2] Assistant Engineer at the Delray Plant, The Detroit Edison Company. Mr. Chatel received the degree of B.M.E. from the University of Michigan in 1914, and after a short period in the research department of the Detroit Edison Company was made boiler-room engineer at the Connors Creek Plant. In 1917 he entered the U. S. Naval Service as an officer in the Engineering and Ordnance Divisions. Upon completion of his war service he assumed the duties of technical engineer at the Delray Plant, The Detroit Edison Company. During the last two years he has been directly in charge of the stoker development at that plant. He is the author of a paper on "Steam Condenser Practice and Performance" presented at the Annual Meeting of the A.S.M.E. in 1927.

Contributed by the Fuels and Steam Power Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

alike as to suggest the question whether the difference was of the same order as the possible errors of estimate.

The absence of any low areas on the Delray site which could have been filled in with powdered-fuel ash and the presence of a local building market which would pay a return of 6.5 cents per ton of coal burned, for stoker ash, formed the basis of the final decision.

The coal-handling equipment and building steel have been

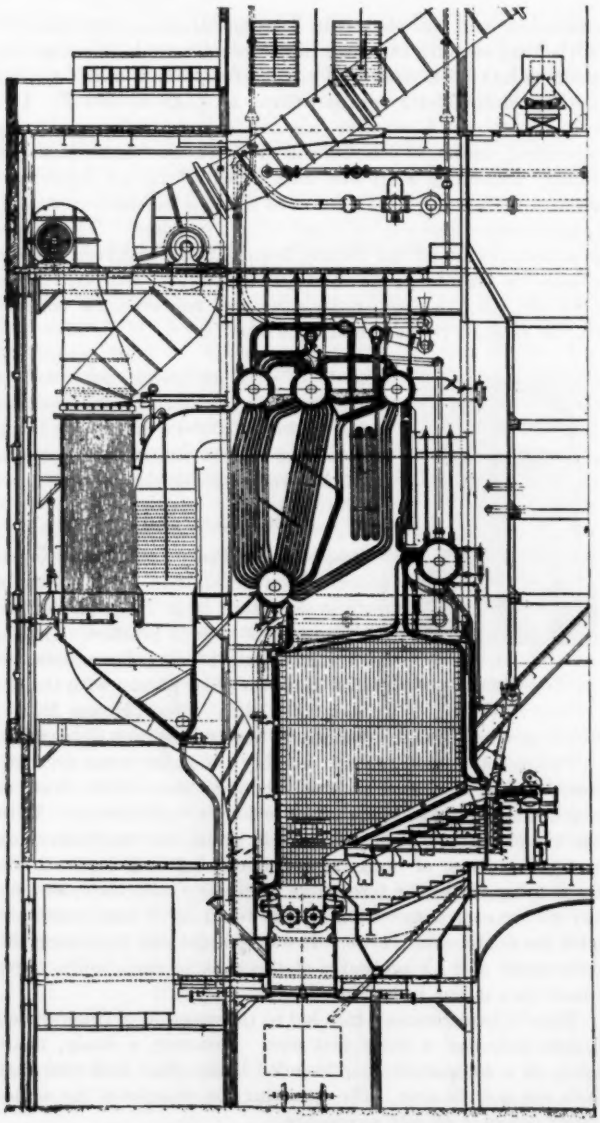

FIG. 1 CROSS-SECTION OF BOILER UNIT AND STOKER, DELRAY POWER HOUSE NO. 3

designed so that pulverized-fuel-burning equipment can be installed should future developments warrant such a change.

Air Supply and Furnace. An upper limit of preheated-air temperature of 350 F was selected as being conservative, although other installations were operating at the time at 400 F or higher. A recent test run, during which the feedwater was bypassed around the economizer, indicated that satisfactory combustion of the general run of coal burned at this plant can be obtained with temperatures closely approaching 500 F. This test was of too short duration (299 steaming hours) to give a definite indication of the effect of this higher preheat temperature on stoker maintenance. An examination of the stoker at the completion of the test showed no burning of parts which could be attributed to the high air temperature, although numerous tuyère plates were found cracked—evidently a result of insufficient allowance for the additional expansion above the normal operating air temperatures.

The problem of proper air distribution, particularly with preheated air under a stoker of this length, was much more complex than had been encountered with previous installations. It was realized that it would be impossible to observe the fuel bed, with the accuracy required, to maintain proper air flow with the hand-operated dampers previously used. The flames from the high-volatile coal would also obscure portions of the fuel bed from any observation doors that might have been installed.

These difficulties were appreciated sufficiently far in advance of this installation to permit an experimental automatic underfire damper control being installed under a stoker at the Marysville Power Plant. Developments of this equipment had proceeded far enough to indicate that a satisfactory arrangement could be worked out for the long stoker, and it was therefore decided to install the automatic air-control dampers under first one, and then the remaining four stokers at Delray.

The combustion chamber was designed with water-cooled walls to eliminate maintenance and increase the steaming capacity. These walls formed the radiant or screen boiler with its water-circulation system entirely separate from the main convection boiler. Above the main furnace chamber and separated by a slag screen was a refractory-lined, secondary-combustion chamber.

The water-wall tubes were covered with various kinds of blocks to temper the cooling effect of the tubes at points where reflected heat was thought to be essential to good combustion. All the front wall tubes, which were bent to form an arch to promote mixing of the lean gas formed at the rear of the stoker with the richer gas liberated at the front, were covered with refractory-faced blocks.

The side-wall tubes were covered with cast-iron blocks to the slag line, and above this point the inner half of the tubes facing the fire was left exposed. The rear wall tubes were covered in the same manner except that the blocks were of the slag-coating type. The upper ends of these tubes were extended over the top of the furnace to form the slag screen previously mentioned.

OPERATION

The 15 retorts are divided into five sections, each section being driven through a two-speed power box. This speed control, combined with a 1-to-4 motor speed and a double-voltage power supply, provides a 12-to-1 crankshaft speed range. This arrangement permits of an accurate coal-feeding rate over a wide range. It is possible with this flexibility to burn only sufficient coal to maintain a floating bank of approximately 50,000 lb per hour, or to generate 430,000 lb of steam per hour. This rate of change of evaporation can be accomplished within a period of less than an hour, provided the boiler is fairly clean and the fuel bed is not too light or irregular at the start.

Rapid changes in coal-burning rates or changes required in sections of the fuel bed are facilitated by the ease with which adjustments can be made to the stroke of the pushers and extension grates. These parts are driven through a bell-crank mechanism in conjunction with each ram, and adjustments are made at the stoker front, outside the plenum chamber. Little time or effort is required on the part of the fireman to make whatever changes are desired.

The individual adjustments of the pusher and extension-grate strokes provide a very flexible means of control. Because of the various combinations afforded by this number of adjustable

units, it is essential to good economy that the operators be able to detect faulty conditions readily and apply the proper adjustments to coal feed, pushers, and fans. Under the present day-to-day load carried on this station only minor and infrequent adjustment of pusher strokes is necessary to obtain good fuel-bed conditions and combustion efficiency. Should there be a sufficient change in the coarseness or moisture content of the coal to affect appreciably the rate of coal burning in a retort or section, it may be necessary to adjust the pusher strokes and the coal-feeding rate to that section. This operation is required, as the automatic dampers which control the air flow over a rather limited range cannot be expected, under such conditions, to keep a uniform fuel bed with an improper fuel-feeding rate or improper movement of the fuel from zone to zone. Appreciable time to correct such defects may be required if allowed to progress, particularly if the correction must originate at the stoker front. The ability to detect faulty conditions at the early stages by observation of the fuel bed or from the operating instruments is quite essential, as irregularities originating at or near the stoker front require more time to correct than on a shorter stoker.

The expected difficulties of fuel-bed observation due to the long flames have more than justified the installation of the automatic air control. This equipment has passed the general development stage, and although refinements are still being made it is now considered a valuable aid to operation.

Under test conditions with and without the air control, a slight advantage is found with the air control in operation. However, under normal operating conditions with similar stokers burning the same coal and operated over a long period, those equipped with air control show a decided improvement. The small difference obtained, with and without the air control during test periods, is the result of the operator's maintaining definite pusher adjustments for any given rating and observing conditions more closely, particularly over the extension grates, than can be expected during normal operation.

The coal, normally burned, is a high-volatile, free-burning West Virginia and southeastern Kentucky mine-run bituminous with an ash-fusion temperature above 2500 F. A typical analysis of this coal is given in Table 1.

TABLE 1 TYPICAL COAL ANALYSIS, DRY BASIS

Proximate analysis:	
Volatile matter, per cent	35.9
Fixed carbon, per cent	56.1
Ash, per cent	8.0
Heating value, Btu per lb	13,750
Ultimate analysis:	
Carbon, per cent	77.4
Hydrogen, per cent	5.1
Nitrogen, per cent	1.2
Oxygen, per cent	7.2
Sulphur, per cent	1.1
Ash, per cent	8.0
Ash-softening temperature, deg F	2500 or above

Little trouble is experienced with clinkers in the fuel bed when proper pusher strokes are maintained. However, improvements have been made to cope with the sheets of slag formed on the side walls and clinkers at the bottom of the tuyère stacks as well as on the extension grates. Special heat-resisting refractories to deflect the slag, formed at high ratings, have been placed in the side walls above the half-tuyères to prevent the formation of slag sheets. The slag runs down over the deflectors and is continuously carried away with the burning coal instead of being built up into large sheets which eventually break loose and foul the fuel bed at the end retorts. The bottom square-ended pushers were replaced with longer beveled pushers which are more effective in cleaning the clinkers from the coal-plate extension and grates.

Stokers are now operated from six to eight weeks before being shut down for stoker or boiler repairs, and it is not unusual to have them on the line for periods as long as three months. Since the plant was started in 1929, it has carried its share of the system load and has continually operated with an average evaporation of 218,800 lb of steam per hour and with a ratio of banked to steaming hours of 24.5 per cent.

Fig. 2 shows the load-duration curve of the stokers for the twelve-month period ending June, 1932. During this period the ratio of banked to steaming hours was 24 per cent.

The movable extension grates, with the parts immediately above and below, have been more susceptible to burning than any other section of the stoker. Redesign of these grate bars to permit freer flow and better distribution of air has reduced the burning appreciably.

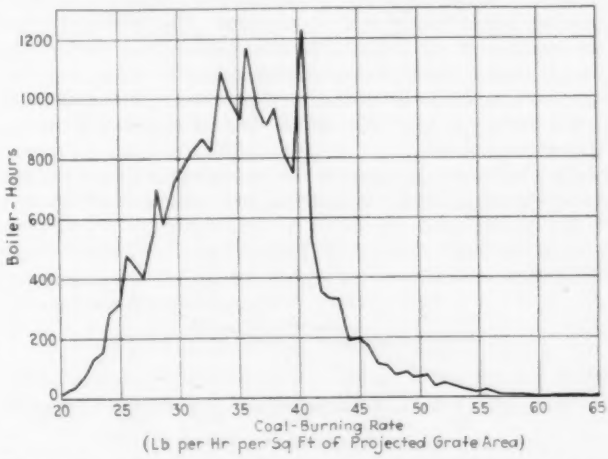

FIG. 2 LOAD-DURATION CURVE FOR STOKERS AT DELRAY POWER HOUSE NO. 3

(This covers all boilers for 12-month period from July 1, 1931, to June 30, 1932.)

STOKER DEVELOPMENTS

The question of stoker developments may well be divided into two parts for discussion. After preliminary operation, it became evident that changes were necessary; first, to improve the combustion and, second, to reduce maintenance, with a resultant increase in continuity of service.

Combustion Developments. The stokers were originally supplied with six square-nosed adjustable-stroke pushers per retort, operated in conjunction with the ram, to push the burning coal, coke, and ashes toward the movable extension grates. With this arrangement the coal was not sufficiently packed at the stoker front and in the retorts, and excessive agitation resulted in smoke. As a result of improper packing, combustion often took place deep in the retorts, which resulted in the burning of iron and the formation of large clinkers over the bottom coal plates and extension grates.

To improve these conditions, lower ram box caps were installed and the bottom pushers were beveled and the nose extended forward as far as practical so that the ends would not extend past the tuyère line on the forward stroke. These changes were an improvement, but it soon became evident that fewer pushers would deepen the retort, produce better coal packing, and enable the operator to maintain a uniform fuel bed with less agitation. Inasmuch as the exact number was questionable, the sectional side cover plates were replaced with one-piece steel plates to obtain straight retort sides, allowing the number and location of pushers to be altered without further retort changes. One stoker was arranged with five pushers and another with four pushers per retort to obtain a comparison.

The five-pusher arrangement showed slightly improved conditions over the original, indicating that it was a step in the right direction, while the four pushers per retort was a decided improvement over the other two. Poorer grades of coal could be handled efficiently. There was less tendency to smoke, and improved construction resulted in a reduction of coal siftings from approximately one-half of 1 per cent to less than one-tenth of 1 per cent. This reduction in quantity of siftings is accounted for by a decrease in the number of joints in the retort construction resulting from replacing sectional castings with one-piece steel side cover plates as well as by the reduction in the number of pushers. Further reduction resulted from a decrease of clearance between stationary and moving parts. The decreased power consumption of the four-pusher arrangement over that of the original design, due to decreased stoker friction and a reduction in excess air, amounted on test to 30 per cent at a steaming rate of 200,000 lb per hour and 38 per cent at a steaming rate of 350,000 lb per hour.

Fig. 3 shows a comparison of the percentage of CO_2 in the flue gas at the boiler outlet obtained on tests of the three different

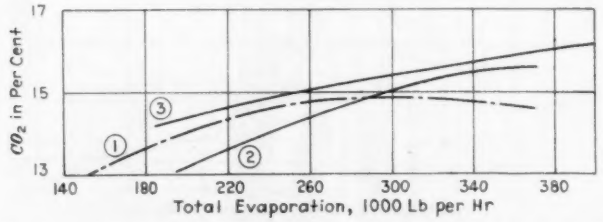

FIG. 3 COMPARISON OF PERCENTAGE OF CO_2 IN FLUE GAS AT BOILER OUTLET

(Test 1, six pushers; test 2, five pushers; test 3, four pushers.)

designs. These data are directly comparable except that better air distribution was provided to the fuel bed and there was less leakage past the control dampers during test No. 3.

Four of the stokers are now equipped with the four-pusher arrangement, while the fifth with the original five-pusher arrangement is still in service.

Design Improvements. The lack of any prior experience with stokers of this size left the designer with only the experience gained from smaller units as a guide. It was to be expected that changes would be required in order to bring the performance of these larger stokers to the same standard of perfection as has been reached through years of development of the smaller units.

After the first few months of operation it was decided to install larger power-box and pusher shearing pins. The forces transmitted through the stoker mechanism had been underestimated and the change was made so that the pins would withstand the normal shearing forces and still give protection to the stoker.

Machine fits and methods employed in driving the pusher mechanisms which had proved satisfactory in smaller stokers were soon recognized as unsatisfactory in this larger stoker. A change was made employing closer tolerances and a clevis-type bell crank instead of the original bar link with cantilever pin. Nearly two years' experience with the improved arrangement indicates that the improved drive needs little attention and the wear on the moving parts is not excessive.

Excessive wearing of the crankshaft journals indicated that the main bearing material was too hard for the material of the crankshafts. Certain gears in the power box also showed excessive wear, and in a few cases pinions were found cracked or broken.

The results of a study to determine the proper material and heat-treatment requirements has been used as a guide in the selection of more adequate materials. The absence of wear on these new parts leads to the belief that there will be no recurrence of this trouble.

The original stoker support plates, made from steel plates 20 in. wide, did not, under the service imposed upon them, provide sufficient strength without sagging. These were replaced with 24-in. steel plates, which were reinforced with the one-piece retort side plates secured to them with close-fitting bolts. This change was made in order to obtain a satisfactory installation of the air-distribution boxes.

Several different types of movable extension grates have been tried, mainly with a view to reducing the amount of iron burned. Better air distribution and cooling of the grates, combined with the ability of the long beveled lower pushers to remove clinkers more effectively, have shown a reduction in replacements.

Changes, other than those made to the extension grates, were incorporated to prevent excessive burning of iron. The stokers were originally supplied with high side-wall air backs which were susceptible to burning. Inasmuch as it was not necessary to supply air at the side walls higher than the plane of the tuyères, these air backs were replaced with standard half-tuyères. Replacements of these half-tuyères are now no greater than that of the full tuyères. Further protection to the side tuyères and the end retorts is afforded by the slag deflectors in the side walls.

The stoppage of coal due to holding up in the supply chutes to any retort has been another serious condition causing burn-outs. Failure of the coal feed to retorts of such depth and length, together with the earlier ignition due to preheated air, has resulted in burn-outs at the stoker fronts. This has been remedied by taking all precautions possible to prevent any foreign matter from being entrained with the coal supplied to each retort. The individual coal chutes to each ram are being replaced with chutes of greater depth which feed to three rams instead of one.

Automatic Air Control. The automatic air-control dampers, which were installed at Marysville as an experiment, were not perfected when the Delray stokers went into operation. Progress was such that it was believed, however, that a design could be worked out that would perform satisfactorily at Delray. This original mechanism was attached directly to the stoker support plates beneath the tuyères, but the coal siftings readily fouled the damper mechanisms, making them inoperative. Correction of this condition was obtained by isolating the moving parts from the siftings with a system of offset air ducts.

This control provides regulation of the air to four zones of each tuyère section. These zones correspond to the sections of the fuel bed controlled by the four pushers, as shown in Fig. 1. Air is supplied from the plenum chamber through an individual control box and air duct to each of the four sections of each tuyère stack, making 56 such boxes per stoker. Neither the side rows of half-tuyères nor the extension grates are equipped with air-control boxes. Additional tests are to be made to determine the advisability of applying such control.

Each control box is equipped with an orifice, a balanced cylindrical damper, and a motor mechanism which regulates the damper opening by power supplied from the drop in pressure across the orifice.

The pressure differential across the orifice, a measurement of the air-flow volume, is maintained practically constant throughout the operating range of the boiler by varying the orifice area. This is accomplished by a separate motor mechanism to which all the orifices are linked.

With the controls in operation and a fuel bed of the desired thickness, the dampers remain balanced. Should a portion of the fuel bed become heavier or thinner, the controls under this particular section will operate to give an increase or decrease of the air quantity. This change will enable the fuel bed to regain its proper thickness, provided the pusher strokes approach the

proper adjustment for the rate and grade of coal being burned.

It has been developed from test that approximately 50 per cent of the total air for combustion passes through the control units, and of this quantity the dampers have a controlling effect up to 20 per cent.

The pressure loss through the dampers amounts to approximately 1 in. of water, which corresponds to a power input of 20 kw to the forced-draft fan.

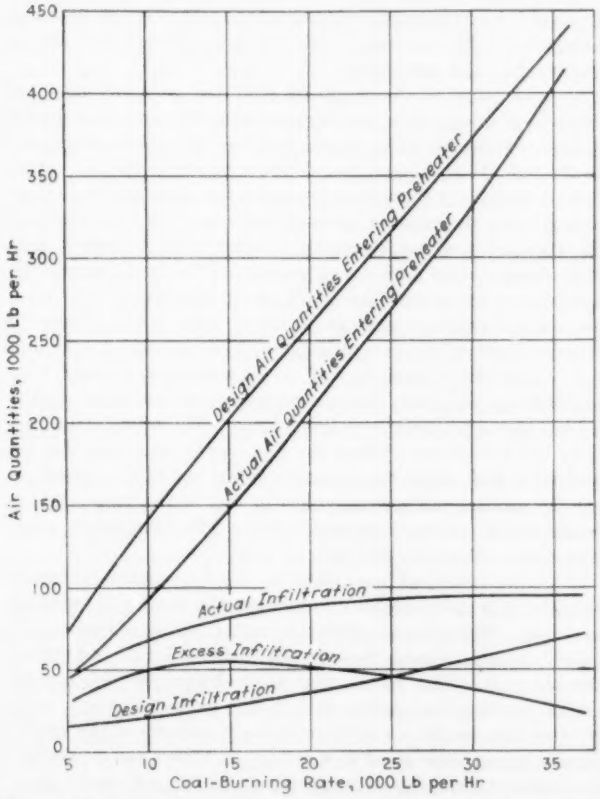

FIG. 4 PREHEATER AIR FLOW AND INFILTRATION-AIR QUANTITIES

STOKER PERFORMANCE

Although the stoker and boiler were designed for a continuous coal-burning rate of 34,000 lb per hour, this rate has been exceeded. It has been possible for intervals of approximately 10 hours, with proper fuel-bed conditions, to burn as high as 45,000 lb per hour.

In Table 2 are given the performance data for maximum and continuous coal-burning rates, based on a coal analysis as given in Table 1. Continuous operation at ratings higher than those given is limited by the accumulation of ash on the slag screen and in the superheater pass. This ash cannot be removed with a hand lance, without reducing the steaming rate.

The overall-stoker, boiler, economizer, and preheater efficiency increased from a yearly value of 82.3 per cent in 1930 to 85.4 per cent in 1931. This improvement is a result of the many changes in design of stoker and air control as well as improvements in operating methods. For the first eight months of 1932 the efficiency is 84.8 per cent, slightly lower than the 1931 figure. Although changes have been made this year that have improved the steaming efficiency, the overall efficiency is less because of the poorer load conditions, with resulting higher banking losses.

Although the gas temperatures leaving the boiler are lower and the CO_2 is higher than predicted, the temperatures of both the flue gases and the air leaving the air preheater are higher than

TABLE 2 MAXIMUM COAL-BURNING RATES

	10 hr	24 hr	Continuous
Boiler:			
Heat output, M Btu per hr per sq ft	15.6	14.5	12.4
Steam output, M lb per hr	430	400	340
Stoker and furnace:	(1)	(2)	(3)
Coal burned, M lb per hr	45.0	41.0	34.2
Coal burned, lb per hr per sq ft of projected grate area	74.0	67.0	56.0
Heat release, M Btu per cu ft per hr	43.0	39.2	32.7
Air to stoker, deg F	378	375	365
Stoker and fan power, kwh per ton	30.3	26.5	21.0

NOTE: (1) Obtained on a stoker having the six-pusher arrangement. It is believed that with the four-pusher arrangement the Beacon Street coal-burning rate of 77.4 lb per sq ft per hour can be obtained. Recent plant load has not permitted a demonstration. (2) This coal-burning rate can be obtained under any expected condition. With favorable conditions this rate may be 45,000 lb per hour. (3) Limited by rating at which boiler tubes may be hand-lanced.

those predicted. This condition appears to be caused by a larger quantity of combustion air being supplied by infiltration and leakage through the ashpit than was estimated for purposes of design of the preheater. The actual air quantities passing through the preheater and through the setting, together with the expected quantities used in the design, are shown in Fig. 4. These quantities were obtained from design data and from a computation of the actual ratio of gas-temperature drop to the air temperature rise taken from operating logs.

AIR CONTROL AT BEACON STREET HEATING PLANT

The stokers under two of the boilers in the Beacon Street Heating Plant have been equipped with manually operated

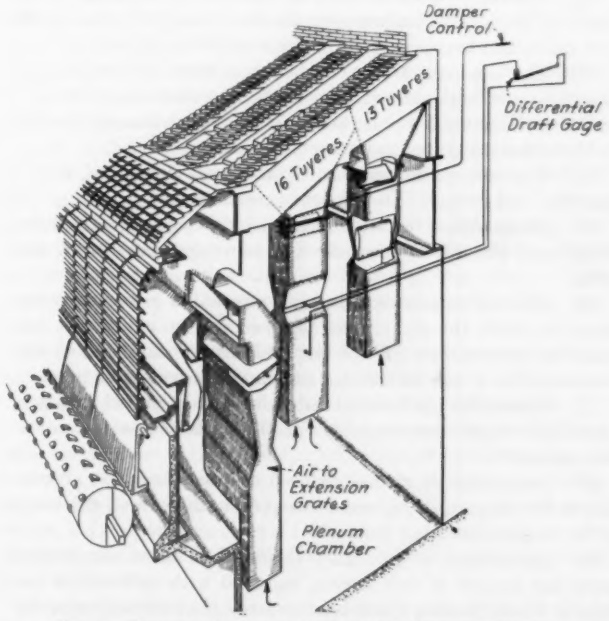

FIG. 5 DAMPER CONTROL UNDER ONE SIDE OF STOKER

metered air control, the general principle of which is quite similar to that of the Delray installation. These stokers are of the underfeed type, 14 retorts wide, with 29 tuyères per retort. There are no air preheaters. Each boiler is served from two stokers which have a combined projected grate area of 636 sq ft, including the common ashpit.

Each stoker is divided into three zones, extending the width of the stoker, for the control of the air. The upper zone is the upper part of the tuyère stack; the intermediate zone is the lower part of the tuyère stack; and the extension grates comprise the lower zone. Each zone of each tuyère section is pro-

vided with a venturi-metering throat and control damper. The extension-grate zone is divided into four sections. A group of differential draft gages, one connected to each venturi-metering throat, is provided as an indication to the operator of the condition of the fire. The control of each individual damper is brought to the boiler gage board so that adjustments can readily be made. Fig. 5 shows the arrangement of this control under one side of the stoker.

The results of tests on these boilers show an increase of maximum steaming capacity of 31 per cent, a maximum coal-burning rate of 77.7 lb per hour per sq ft of projected grate area, including the pit, and a calculated increase in overall efficiency of $^1/_2$ per cent at high loads and about 2 per cent at low loads over a similar boiler without the air control.

At a steaming rate of 400,000 lb per hour, 83 per cent of the total air supplied by the forced-draft fan is metered and controlled by the air-control apparatus. The remainder represents leakage into the furnace through the walls, around pushers, and up through the ashpit. The greater portion is supplied through the lower tuyère section, while about equal amounts are supplied through the upper tuyère zone and the extension-grate zone.

Conclusions

Developments, as a result of operating experience, have led to the following improvements in the design and operation of the Delray stoker:

(1) A change from a six- to a four-pusher arrangement has made it possible to burn efficiently a wider range of fuels.

(2) Clinker formation has been reduced by a change in the shape of the bottom pushers, installation of slag deflectors in the side walls, and better packing of the coal in the retorts.

(3) The amount of iron burned has been reduced by the elimination of high side-wall air backs, the installation of side-wall slag deflectors, more certain coal supply, and improvements to the extension grates and other parts of the stoker.

(4) The automatic air control has been developed into a practical and useful aid to efficient combustion.

(5) Maintenance has been reduced by changes in mechanical design and the use of adequate and properly heat-treated material.

(6) The continuous coal-burning rate of 56 lb per sq ft per hour for which the stoker was designed can be easily met and could be exceeded were it not for the limitation imposed by the accumulation of ash on the slag screen and superheater tubes.

(7) One stoker has been operated for a short period with preheated-air temperatures as high as 500 F without loss of combustion efficiency.

(8) Infiltration of air has reduced the expected heat absorption in the air preheaters, and consequently the overall efficiency of the steam-generating unit.

(9) Installation of manually operated metered air control under the stokers of two boilers, supplied with cold air, in the Beacon Street Heating Plant has increased the steaming capacity 31 per cent and the boiler efficiencies from $^1/_2$ to 2 per cent.

Discussion

Bert Houghton.[3] That the authors' opinions differ radically from mine as to the proper design and operation of stokers does not in any way detract from the excellence of their paper. The basic disagreement is the stress laid upon the deep retort and densely packed coal in the retort, which they claim enables the operator to maintain a uniform fuel bed.

While they have been operating these stokers for three years, all improvements possible, particularly those to improve combustion, have not been completed. The writer does not believe these improvements ever will be completed until they shallow the retorts and do not pack the coal so tightly. With a stoker of large area, the thin, even fuel bed is best for normal operation, and it can be brought up to high continuous ratings much quicker than a thick fuel bed.

The writer has run two boilers side by side—one with a thick fuel bed and deep retorts and the other with shallow retorts and a thin fuel bed. The results vindicated the reliability at maximum ratings of the thin fuel bed and the ability to maintain high ratings continuously and uniformly.

Another point of disagreement with the generally accepted methods of firing is the maintenance of a balanced draft in the furnace. Experience has taught that the manner of getting the air through the fuel bed is best done by pulling it through rather than by pushing it through. To obtain the best results we must have an even thickness of the fuel distributed over the fuel bed. The air must be drawn through the bed in order to keep it light and porous. Deep retorts give an uneven fuel bed, causing the burning coal to separate into dark and bright lanes. The dark lanes in the retorts form logs of seared coke, which appear to be huge clinkers, but in reality have an inner core of coke and coal. After these dense logs of seared coke have formed, they tumble down irregularly over the rear end of the stoker, giving the fuel bed the appearance of a brush heap. The bright lanes just above the tuyère rows where the fuel bed is relatively thin let the greater part of the air through the fuel bed at that point, so that the air does not pass through the fuel bed in proportion to the amount of coal to be burned. These difficulties can be overcome with a thin, even fuel bed.

To obtain increased quantities of steam or higher ratings of the boiler it is only necessary to increase the draft and speed up the stoker. The point at which the draft should be placed at zero referred to atmospheric pressure lies within the fuel bed rather than above it. This means that air is drawn through a good part of the fuel bed rather than being pushed through, with the attendant trouble of uncovering large sections of the grate.

It is common experience that ratings on boilers can be materially increased when the boiler passages and furnace can be scavenged of the hot gases. Where underfire pressure is depended on, the furnace and boiler passages choke up, and with increased pressure under the fire there is actually a decrease in boiler output.

Some people have argued that the maintenance of a high draft in the furnace would require a large increase in the size of the induced-draft fans to handle the larger quantity of hot gases. However, for an increase of minus $^1/_2$ in. to minus 1 in. in draft in the furnace, the increase in gas volume at the induced-draft fan inlet is rather small, ordinarily not amounting to more than a fraction of a per cent, and while there is an increase in the induced-draft fan power, this is more than offset by the consequent reduction in the forced-draft fan power. The thin fuel bed also cuts down the auxiliary power of both induced- and forced-draft fans due to the lesser resistance in the fuel bed. The writer has also been operating stokers equipped with preheated air, with high induced draft, and finds it not only lowers the stoker maintenance, but in this case also cuts down the amount of auxiliary power.

There are two very definite schools of thought on stoker design and operation. This divergence of opinion is a healthy condition. It will lead to a greater understanding of the design and operation of the larger stokers which we have today and of those of the future, which may be even larger. The stoker has come back into its own after having been handled rather roughly for a time by pulverized-fuel installations. The cost of coal prepara-

[3] Operating Superintendent, Brooklyn Edison Company, Brooklyn, N. Y. Mem. A.S.M.E.

tion and maintenance of the mill is far in excess of stoker maintenance per ton of coal burned.

H. D. FISHER.[4] Our experiences have been similar to the authors', and we trust will be improved by similar remedies. We have operated an underfeed stoker equipped with clinker grinder (not of the make described in the paper), of 160 sq ft projected area of underfeed and overfeed sections and 207 sq ft total projected area, for about 3½ years, burning Beckley seam New River coals at rates of 5000 to 6500 lb per hr, the load being practically constant day and night for three- to six-day periods, the variation in capacity being mostly seasonal.

We have found that by far the largest part of the stoker maintenance is required in the high-side tuyères, in the overfeed grate tuyères at the bottom of the retorts, and in the agitator grates at the edge of the clinker pit. During the first 22 months of operation the replacement of sidewall tuyères averaged 0.62 set per year and agitator-grate fingers 1.8 sets per year, while during the next 13 months' operation, at a slightly higher rating, these were, respectively, 1.0 set and 1.9 set per year. The replacement of the overfeed-grate tuyères was too irregular to allow of averaging, but was at a lower total rate than either of the foregoing. Gear-box bushings and shafts have been replaced once, but the gears and jaw clutches showed negligible wear, and no trouble has been found with crankshaft or wristpin bearings. Cost of repair parts was for the first period $0.0453 and for the second $0.0526 per ton of coal burned.

The paper confirms the writer's opinion that sidewall tuyères should be eliminated, and he would appreciate it if the authors will describe in more detail the slag deflectors in the sidewalls, only casual mention of which is made.

J. S. BENNETT.[5] The authors' paper touches on two subjects of vital interest to the power-plant designer; namely, fuel-burning rates per unit of area and the use of highly preheated air with underfeed stokers. With the whole tuyère area of the stoker supplied from a common plenum chamber, the greatest air flow takes place through the spots offering the least resistance to the air flow. This greater air flow burns coal in these areas rapidly, still further reducing the resistance to air flow. This condition may be exaggerated by uneven coal flow from the bunkers.

With air control, the whole stoker area is divided into a number of rectangles. The quantity of air flowing through each rectangle is metered, and if the flow through any section is greater or less than any other section, the rate of flow through that section is modified to bring it in line. The uniform flow through each band across the stoker insures uniform burning and freedom from uneven spots.

The air flow through each section with manual air control is indicated on a gage board. It is a simple matter to increase or check the air flow to any area by control buttons. Automatic control employs the same impulse that operates the gage with manual control to increase or check the air flow.

Air is controlled across the stoker in bands. It is not necessary and is frequently undesirable to have the same air flow through adjacent zones going down the stoker. For example, the air flow through the top 17 tuyères in the stoker may be only half of the air flow through the next lower 17 tuyères, but the air flow through each row of the top 17 tuyères on the stoker should be the same. The need for some form of air regulation has been apparent, but there have been many practical difficulties to be overcome.

[4] Plant Engineer, New Haven Pulp and Board Company, New Haven, Conn. Mem. A.S.M.E.

[5] Mechanical Engineer, American Engineering Company, Philadelphia, Pa. Mem. A.S.M.E.

Air control of the types described by the authors has passed the experimental stage and is now in commercial use in three large central stations under eight boilers. Its use will undoubtedly spread rapidly, as its benefits become fully appreciated, not only in new plants, but in gaining increased capacity in old ones.

Air control has a double purpose; first, to raise the average fuel-burning rate for the whole stoker, while limiting the maximum fuel-burning rates in small spots, and, second, to distribute the air in such fashion that those sections of the fuel bed capable of very high fuel-burning rates are not limited by other sections of the fire, which cannot produce correspondingly high fuel-burning rates.

A conventional stoker is limited in capacity by small spots of excessive fuel-burning rates, equaling 250 lb per sq ft per hr, although the average rate may be only 60 lb per sq ft for the whole stoker. Air control holds the burning rate in any spot close to the average for the whole stoker.

It is hard for a man that has not seen the performance to realize that a stoker burning from 70 to 80 lb per sq ft per hr as an average with air control is not working any harder than the same machine without air control at fuel-burning rates of from 40 to 50 lb per sq ft per hr.

This company has been conducting an exhaustive study of fuel-burning rates using zoned air control. We have found that an average fuel-burning rate for the whole stoker in excess of 90 lb per sq ft per hr can be maintained. This study was conducted on a unit equipped with an air preheater, which supplied air for combustion at from 500 to 570 F. The maximum air temperature which could have been used successfully is not known, as the construction of the heat-recovery equipment did not permit the use of a higher air temperature.

The uniform fuel bed produced by air control would be expected to produce uniform temperatures in a stoker structure. This is confirmed by the fact that a study made by placing 24 thermocouples in the tuyères and other parts of the stoker exposed to the greatest temperature showed average metal temperatures of 600 deg with air temperatures averaging 530 deg and with normal peak temperatures of the metal running from 800 to 900 deg, when the stoker was burning 70 lb of coal per sq ft per hr. These temperatures are considerably lower than similar temperatures which have been obtained on cold-air stokers without air control.

Because it limits the maximum fuel-bed temperatures by limiting the fuel-burning rate in spots, air control is of great value in burning coals containing ash with low fusing temperature.

The authors' statement that it has been found that double-fired units are no more costly than single-fired units should be of great interest to engineers contemplating very large steam-generating units. The authors seem to be supported in this by present practice in large steam-generating units, as it is a notable fact that all units generating over 600,000 lb of steam per hour are fired from both ends.

It is interesting to note that the Delray unit, if double-fired, would give at least 860,000 lb of steam per hour.

JOSEPH G. WORKER.[6] It might be of interest to go back into the history of the development of the boiler and stoker units at Delray No. 1 and No. 2, and then to Delray No. 3 in order to see just what progress has been made.

The conception of the large 2365-hp boiler units in Delray No. 2 design came from a suggestion of Dr. Patchell and experiences at Delray No. 1. This design of Delray No. 2 established a principle of engineering that was persistently adhered to in later plants. These were the largest boilers in the world at that time.

[6] American Engineering Company, Philadelphia, Pa.

This principle of double-ended firing has been followed with all methods of fuel burning for large-capacity units. None of the large units are what might be termed single-fired units; they all follow the Delray No. 2 duplex-firing method.

In the year 1911 a series of tests were conducted on the boilers and stokers at Delray No. 2. These tests were under the supervision of Mr. Alex Dow, past-president of the Society and president of the Detroit Edison Company, aided by Dr. Jacobus and a corps of engineers of national prominence.

Delray No. 2 tests do not exceed 40 lb of coal per square foot per hour or a steaming capacity of 150,000 lb of steam per hour, while Delray No. 3 burned 74 lb of coal per square foot per hour at 430,000 lb of steam per boiler per hour.

The authors state that the boiler-plant cost was as low as any other method within their experience.

The manufacturer of the stokers offered the air control as described by the authors in order to speed up operation to burn 70 or 80 lb of coal continuously per square foot of grate per hour instead of 35 or 40 lb.

The tests in 1911 show that a daily average of about 6000 kw was carried by one of the 2365-hp boilers with 7000 kw, or 8000 kw as a peak. Each boiler at Delray No. 3 carries 34,000 to 40,000 kw, even though the boilers at Delray No. 3 are not much larger in heating surface than the boilers at Delray No. 2.

The figure that the authors mention of 85.4 per cent as the average yearly efficiency is about the predicted guaranteed efficiency at the average operating steaming capacity for the year.

The authors have shown rare judgment and courage in using designs that have in their experiences seemed best to suit their needs, irrespective of engineering fashions.

E. L. Hopping.[7] The paper's treatment of the development in stokers, both in the Delray Power House No. 3 and in the Beacon Street Heating Plant, shows that there has been a marked increase in the coal-burning capacity per square foot of stoker area. This development should add to the possibilities of lower investment cost where stoker capacity is a limiting factor. The zoned air control with manual operation was first applied at the Beacon Street Heating Plant and offers a solution to the control of the fuel bed, which is particularly useful with very wide and long stokers where the usual operating methods depending largely on personal observation are inadequate. At high burning rates the flame density prevents observation of the fuel bed for more than a few feet beyond the observation doors.

There has always been an opinion among power-plant engineers that stokers would not successfully burn the same types of coal that could be used in pulverized form. Stoker manufacturers advised this company's engineers early in 1931 that this was not the fact, and after a visit to the Detroit Edison Company's Beacon Street Heating Plant it was decided to make an experimental installation with zoned air control manually operated on No. 8 boiler at Chester Station. It was hoped to demonstrate not only that the cheaper coals which are available to pulverized-fuel installations could be burned satisfactorily on stokers, but that they could also be burned at higher rates than was the usual practice with better coals. The results of tests made in 1932 on this experimental stoker are offered in discussion of the paper, as they supplement data given therein and it is believed they will be of value to the industry.

No. 8 boiler, which is a 14,217 sq ft Stirling boiler with a 50,276 sq ft tubular preheater, was installed in 1925. The original furnace was entirely of refractory construction. The unit was fired with a 15-retort, 21-tuyère stoker of 310 sq ft projected area and having an ashpit 3 ft 8 in. wide and 5 ft 3 in. deep. A paper presented by Mr. N. E. Funk to the Power Division of this Society at its May meeting in 1926[8] describes tests conducted at that time.

Because of the effect of the high preheated-air temperatures, which reached a maximum of about 600 F, maintenance costs were very high with the refractory furnace walls, and to correct this condition the bridge wall and portions of the two sidewalls were rebuilt with bare steel water-cooled blocks. Tests were made on the unit with this construction and with refractory surfaced blocks, the results of which were published in the Prime Movers Committee Report on Stoker Equipment and Furnaces, N.E.L.A. Publication No. 068, in June, 1930. This showed some improvement in performance, particularly at what was then the maximum continuous boiler output of about 150,000,000 Btu per hr.

The experimental stoker previously mentioned, which was placed in operation in March, 1932, is only 11 retorts wide and 33 tuyères deep, with a projected area of 295 sq ft, and has an ashpit 3 ft 2 in. wide and 6 ft 10 in. deep. It has a diverging slope from the throat to the crusher rolls, which are 18 in. in diameter instead of the 10-in.-in-diameter rolls used with the old stokers. It was necessary to restrict the width of the stoker in order to permit operation at high burning rates because of the limitation in steaming capacity of the boiler unit, which was fixed at approximately 200,000 lb per hr, equivalent to an output of about 240,000,000 Btu. To accommodate this narrow stoker it was necessary to construct a considerable bench in the side wall. A slag lip was provided on each of the side walls and at the top of the bridge wall. These slag lips minimized slag formation along the side and bridge walls. The stoker is provided with sectionalized air control in three zones. The first zone takes in approximately the upper half of each tuyère bank and provides 11 individual air inlets with adjustable throats and manually operated dampers. The intermediate bank is similar to the first, but is applied to the lower part of each tuyère bank. The third zone takes in the extension grates and is divided horizontally into three compartments, each with its own adjustable throat and manually operated damper. The damper in each air inlet is controlled by a pushrod located on a control panel. The panel is also equipped with differential pressure gages that indicate relative flow through all the air inlets.

One ram and two pushers were originally installed in this stoker, but after experimental runs the two pushers, each of which was 10 in. in height, were replaced by three pushers, each only 6 in. in height. This alteration resulted in considerable improvement in the fuel bed and materially reduced burning of tuyères and side plates.

In the first experimental runs there was a substantial amount of soot deposited at the rear of the boiler and at the bottom of the preheater. A considerable quantity of the particles blown from the fuel bed also deposited against the bridge wall. In an effort to improve the stoker efficiency, soot was removed from the rear of the boiler and the preheater and deposited in a hopper above the boiler; then fed by gravity back into the stoker hopper. To prevent the piling up in the fuel bed at the bridge wall, air was introduced between the water-cooled blocks in this wall about at the normal level of the fuel bed. This air permitted almost complete combustion of the material and improved operating conditions at this point. So far as could be determined by test, the introduction of air in the bridge wall had no effect on the CO_2.

A series of tests indicated that the best operating conditions were obtained when the relative air ratios through the controlled zones were 15 per cent through the first zone, 50 per cent through

[7] Mechanical Engineer, Philadelphia Electric Company, Philadelphia, Pa.

[8] "Comparative Performance of Air Preheaters," by Nevin E. Funk, Trans. A.S.M.E., 1926, vol. 48, p. 337.

the second, and 35 per cent through the third, or extension-grate zone. Analysis has indicated that about 65 per cent of the total air for combustion entered the furnace through these controlled zones, 15 per cent through the bridge wall air boxes, and 20 per cent by leakage through the stoker.

The tests for the new stoker were all made with the foregoing air ratios with soot returned to the hopper and with the air admission through the bridge wall. The soot returned was not included as part of the fuel.

Attention is called to the 500-deg air temperature leaving the preheater, which is somewhat unusual for good performance with stoker firing. The tests have indicated that no serious increase in maintenance cost would result from continued operation with this temperature.

With the old stoker the maximum output was about 150,000,000 Btu per hr, which may be considered as a continuous rating, since the tests were 24 hours in duration. On the new stoker the maximum output was 250,000,000 Btu per hr, but the conditions in the fuel bed indicate that these ratings could be maintained satisfactorily only for periods of about 4 or 5 hr. At the end of that time there was an excessive amount of smoke emission from the stack. Because of load conditions at the plant it was not possible to run the tests on the new stoker for greater duration than 10 hr, but from the condition of the fuel bed at the end of the lower rating tests, it is believed that a continuous output of at least 215,000,000 Btu can be maintained with satisfactory operation. This represents a dry-coal burning rate of 60 lb per sq ft of projected grate area, which is a substantial increase over the 45 lb burning rate possible on the old stokers.

It appeared that feeding soot with the coal to the grate tended to increase CO in the furnace and also appeared to slightly increase the fly refuse loss up the stack. This increase in CO and fly refuse loss, however, was greatly overbalanced by the saving accruing from returning the soot. The CO observed at the boiler outlet varied from 0.03 to 0.3 per cent, while the CO_2 was fairly constant in the tests at about 15 per cent.

Since the test runs were for periods of 10 hr or less, the radiation and unaccounted-for losses were estimated. The estimates, however, were based on former tests conducted on this boiler, and the efficiencies thus secured were checked by efficiencies based on measured coal and water.

The maintenance cost as indicated from the test period was not excessive as compared to any of the other stoker installations on the system. Carborundum plates have practically eliminated the burn-out trouble previously experienced on extension grates. Some tuyères were burned at the point immediately over the division between the first and second air zones, where it is possible that the higher air pressure in one zone caused a down draft into the adjacent zone. The manufacturers believe that trouble at this point, although not serious, can be reduced.

This stoker demonstrated its ability to burn some of the cheaper coals carrying ash with low-temperature softening characteristics, which are available in this territory but heretofore could not be satisfactorily burned on stokers. The coal selected and used in the tests was a Central Pennsylvania coal having the following proximate analysis:

Moisture, per cent	4.5
Volatile (dry basis), per cent	20.1
Fixed carbon (dry basis), per cent	74.0
Ash (dry basis), per cent	5.9
Sulphur (dry basis), per cent	1.4
Heat value of coal (dry basis), Btu	14,800
Initial softening point of ash, deg F	2100
Final fusion point of ash, deg F	2550

This coal was selected from among a number that were satisfactory for slag-tap pulverized-fuel furnaces but not for stoker firing, and has a price range of 25 to 40 cents per ton lower than that for good stoker coals. During experimental runs on the stoker, this particular coal gave a great amount of trouble. It produced clinkers which fused to the tuyères and the side plates of the stoker, resulting in excessive burning of stoker parts, and it was difficult to maintain a satisfactory fuel bed. It differs from good stoker coals principally in the initial softening point of the ash, which is about 2100 F, whereas the coals which are burned successfully on standard stokers have ash with an initial softening temperature which is usually above 2400 F, or within 100 to 150 deg of the fusion temperature of the ash.

The experimental runs were made with this coal and with two good stoker coals, resulting in an efficiency at 240,000,000 Btu output of about 70 per cent with the coal used in the final test and 74 per cent with the good stoker coals. In the final tests there was a substantial improvement in the performance where at a rating of 240,000,000 Btu an efficiency of about 82 per cent was obtained.

Summarizing the improvements in the stoker and related apparatus, it is found that the efficiencies at high ratings are the result of the following changes as compared to the older stokers:

1 Use of carborundum plates on the extension-grate section
2 Use of larger clinker grinders with deeper ashpits having diverging slopes and with positive crushing between the extension grates and the bridge wall
3 Zoned air admission with control and indicated performance on a panel in front of the boiler
4 Deeper ram boxes and better fitted interior parts
5 Improved pusher design with ability to increase or decrease the stroke of each individual pusher from the front of the stoker
6 Reclamation and burning of soot which normally is thrown away with the ash
7 Introduction of air at the bridge wall which completes the combustion of particles blown to this section of the fuel bed
8 Use of slag lips on the side and rear walls to prevent accumulations along the side and back of the fuel bed
9 General improvements in mechanical strength of stoker parts.

P. Nicholls.[9] This discussion will be confined to the fuel bed and the authors' description of the changes made to the stoker. In common with the majority of papers that deal with underfeed stokers, this one describes the changes made and gives the relative over-all results obtained before and after the changes, but does not tell the reason why they were made or the line of argument that suggested that improvement in operation would result.

If one is dealing with overfeed or hand-fired furnaces, the changes are related to the burning action in the fuel bed, to the gases arising from it, or to the mixture of these gases with secondary air, which factors again the authors may relate to the fuel being burned; also the logic of the changes may be more or less explained. Problems connected with gas producers and with powdered fuel are usually treated in a similar manner.

The reason for this difference is that we have a fairly clear conception of the process of combustion in these types of burning, but there is no corresponding knowledge of underfeed burning. It may be that those connected with the design and operation of underfeed stokers know more than they tell, or is it that they have to depend on guess and on trial and error? At least the lack of reasoning makes it difficult to follow and to classify the data given in papers, and leaves one in the dark as to whether

[9] Supervising Fuel Engineer, Pittsburgh Experiment Station, U. S. Bureau of Mines.

the lessons taught can be applied to other conditions and other coals.

It is granted that the actions in a fuel bed of an underfeed stoker are much more complex than those in an overfeed and that the burning is a mixture of overfeed and underfeed. In other types of burning the travel of the pieces of fuel can be followed, but the writer has not yet seen more than an approximate suggestion of the paths followed in an underfeed stoker. As previously stated, the actions could only be completely covered by tracing the life history of the various streams of coal from the time they leave the pusher to their discharge as ash; this would include their ignition and the loss of combustible as related to their location.

The U. S. Bureau of Mines investigated the process of combustion in overfeed burning, and the results, published in Technical Papers 137 and 139, have been referred to as classics by a recent writer.[10] We have desired to supplement this work by a similar study of underfeed burning; the complexity of the problem and its many graduations were a deterrent, but an investigation has been under way for some time, and it is expected that a first report will soon be presented. Because of its complexity, a start was made by studying pure down-burning without side flow of the fuel; combined with this work has been a study of the effect of preheated air on the combustion of both over- and under-feed beds—another subject on which data are lacking.

It is evident that the factor of rate of ignition of the fuel is all-important; a fuel cannot burn any faster than it is ignited, and the rate of ignition is not proportional to the rate of air supply, whereas the rate of burning is approximately so until such a high rate is reached that the fuel bed becomes so thin that the oxygen is not consumed and excess air appears in the gases. Although the actions in an underfeed stoker are far from being a pure down-burning, yet this principle underlies them and an understanding of it should be a guide in interpreting observations and planning changes.

It would be helpful if the authors could explain the line of reasoning followed in making the changes to the Delray stokers. Was it possible to predict that the motion of and the burning of the fuel could be improved by modifying the motion of the entering coal?

FRANK S. CLARK.[11] Any one who has visited the Delray Station cannot but recognize the care and thought put into the design of the plant and also appreciate its scrupulous cleanliness. Where there is good housekeeping, there is invariably good operation.

There are a few questions which the writer would like to ask. It is stated that "considerations which led to the selection of single-ended boilers indicated a lower first cost. However, a study made later on a comparable double-ended boiler plant indicated that such was not the case. The operating convenience of the single-ended design is its only advantage." Were the comparisons made using a Stirling-type boiler only or was the sectional header boiler considered? It is appreciated that the Delray Station was designed about four years ago and that considerable advance in the art of combustion has been made since that time. The writer would like to know, however, if a low rate of heat release in the furnace was assumed or if the analyses were made on the basis of the higher heat-release rates such as are now feasible.

In relation to the method of fuel burning, whether in pulverized form or on stokers, it is stated that "Estimates of required investment for the two types of plants indicated total costs so nearly alike as to suggest the question whether the difference was of the same order as the possible errors of estimate." Were these comparisons made using the bin and feeder system for pulverized coal and, if so, was the preparation plant housed in a separate building as is the case at Trenton Channel? With the pulverized coal, was an extremely moderate rate of heat release considered, as is the case at Trenton Channel, or were the comparisons made on the basis of some of the more modern forms of forced-draft pulverized-fuel burners with high furnace-heat release?

Fig. 2 shows a load-duration curve for the stokers for all boilers for the 12-month period from July 1, 1931, to June 30, 1932. The continuous rated capacity of the stokers is given as 56 lb per sq ft of grate surface per hour. Referring to Fig. 2, one sees that the stokers were run at this rating for a total of only about 40 hr during the year. Were any measurements taken of the amount of coal blown from the grates when burning coal at the rate of 56 lb per hr; also, was the very small use of the continuous fuel-burning capacity of the stokers due to the conditions of the load or to some others such as the accumulation of ash on the slag screen and superheater tubes as is mentioned in item 6 of the conclusions? What measures do the authors consider necessary to take in order that the continuous fuel-burning capacity of the stokers might be attained over long periods of time?

I. E. MOULTROP.[12] The authors' study of the relative advantages of stokers versus powdered-coal equipment for their conditions shows that the two types of fuel-burning equipment are about on a par. This is not surprising to some of us who have been carefully watching the developments in both powdered-coal equipment and stokers.

It is of great value to have on record the statement of the engineers of so successful a large utility as the Detroit Edison Company that there is very little difference between the two types of fuel-burning equipment and that the decision is governed by the disposal of the by-products, This is most gratifying to those engineers who have had faith in the stoker and have had the courage to carry on with it in the face of a popular hysteria for powdered fuel.

Now at a time when no one is increasing his plant or putting in new equipment, we can sit down and think over the advantages and disadvantages of the various types of fuel-burning equipment in advance of future needs. The opinion seems too general that each type has its advantages and disadvantages and that the choice will have to be governed largely by local conditions.

The efficiency of the stoker when properly designed and operated has always been good, but there has been ground for improvement in maintenance cost. Apparently the Detroit Edison Company has done much in this direction. The most notable improvement, and one which will have far-reaching effects, is the air control to the fuel bed. When one considers that the modern stoker having an area of 200 sq ft or more is placed above a plenum chamber with a uniform pressure of air in it, is it any wonder that adequate control of the fire is lacking? The slightest variation in the thickness of the fuel bed will immediately change the air distribution in the wrong way. If there is a spot in the fuel bed that is a little thinner, then much more air will rush through, whereas the supply should be reduced to avoid burning a hole. Conversely, the same thing is true when the fuel bed becomes thickened in a locality.

With this condition it is not surprising that maintenance of stoker parts in contact with the fire is heavy. Proper air control should not only practically eliminate this defect, but should

[10] "On the Mechanism of the Combustion of Fuel in Industrial Furnaces," Prof. Morris W. Travers, Jour. Inst. of Fuel, vol. 6, Oct., 1932, pp. 45–48.

[11] Consulting Engineer, Boston, Mass.

[12] Chief Engineer and Superintendent of Construction Bureau, Edison Illuminating Company, Boston, Mass. Mem. A.S.M.E.

improve the economic performance. The thin spot tends to permit high excess air and lower the CO_2.

Manual control of the air is a long step in advance, but what is really needed, and it is going to come in time, is an automatic control which will insure that every square foot of fuel bed will have automatically supplied to it the exact amount of air required. When this is done, we will have a very much improved stoker performance.

There has been much discussion lately as to the relative advantages of the thin versus the thick fire on the stoker. The manufacturers and most of the users believe in the fairly thick fuel bed.

The tendency of the present day to install very large boiler units has forced the engineers to either use powdered fuel or to put in abnormally large stokers. There has been a tendency to increase the size of the stoker too rapidly, as materially lengthening the stoker brings in factors of unknown value and difficult to meet in operating.

The alternative is to put in short stokers, one at each end of the boiler. When the first installation of this kind was made at the 59th Street Station of the I.R.T. by the late Mr. H. G. Stott, the writer thought the principle was a mistake and would lead to increased investment costs. Mr. Stott undoubtedly did the only thing he could to get increased output from his boilers, but there have been very few double-end installations made unless there has been some controlling factor demanding it. The writer wonders if Mr. Stott was not looking farther ahead than we realized, and if, in place of some of these tremendously long stokers recently installed, it would not have been better to put in two much shorter stokers, thereby keeping the fire under better control, even though the fuel-supply system was a little complicated and the installation cost perhaps a little higher. This is a subject that should be carefully studied by engineers where they have a problem of furnace design for a very large boiler.

It is noticed in the technical press that engineers on some of the recent power plants across the water have expressed the thought that the stoker or the powdered-fuel equipment, as the case may be, was the controlling factor of the evaporating plant and that they are showing a tendency to put the responsibility for the boiler-room installation on the manufacturer of the fuel-burning equipment. This is going a little too far in taking the responsibility off the boiler manufacturer and placing it on the stoker men, but the idea behind the thought is good.

Power-plant engineers have been too prone in the past to not sufficiently consult the stoker builder before determining on the boiler, superheater, and economizer. The stoker manufacturer is vitally interested in what is going to be put above his stoker to evaporate the water. The proportions of the evaporating apparatus and their relative location have a bearing on the fuel-burning equipment, and the advice of the stoker manufacturer should be sought and given equal weight with that of the boiler manufacturer.

H. E. KLEFFEL.[13] Can one at the present time sell the stoker ash at a rate of 6.5 cents per ton of coal burned?

Referring to Table 2, the coal-burning rate in pounds per hour per square foot of projected grate area for 10 hr is 74 lb, for 24 hr 67 lb, and for continuous operation 56 lb; the continuous coal-burning rate is limited according to item 6 of the authors' conclusions by the accumulation of ash on the slag screen and superheater tubes, and as this accumulation is due to the fine particles of coal, coke, and ash being carried up through the furnace by the gas stream, have the authors considered screening the coal and providing the stokers with fuel of a given size range and using the fines in their pulverized-fuel-fired plants? This is a question of balancing the gains, if any, against the cost of screening, handling, and transportation.

[13] New York, N. Y. Assoc-Mem. A.S.M.E.

At the Delray Plant the maximum continuous burning rate is 56 lb per sq ft of grate per hr, with a heat release of 32,700 Btu per cu ft per hr, whereas at the Beacon Street Heating Plant the maximum continuous burning rate is 77.7 lb of coal per square foot of grate per hour, with a heat release of 41,100 (see p. 283 of December issue of *Power*). It would be interesting to have a comparison of the two furnace designs and an outline of the arrangement of the furnace heating surface and the boiler heating surface exposed to the furnace of the Beacon Street Heating Plant boilers, and the authors' suggestions as to how the Delray furnaces could be rearranged to overcome the limitations imposed on the stoker.

AUTHORS' CLOSURE

The preference expressed by Mr. Houghton for a thin, porous fuel bed with the combustion air drawn through it, rather than forced through it, indicates that he may have in mind an extremely heavy fuel bed. The authors agree that a fuel bed can be too thick and too densely packed for best results, but it is apparent that a thin fire with high gas velocities is the other extreme.

The thickness of a fuel bed for best economical and operating results depends largely upon local conditions. The type and size of stoker, kind of coal burned, fan capacity, and the excess-air requirements are items which have a bearing in determining the proper fuel-bed thickness. Although the deepened retorts at Delray result in more coal packing, there are no "dense logs" and control of the fuel bed has been definitely improved. The time required to obtain the maximum boiler rating has not been decreased and the efficiency has been increased.

With a normal fuel bed the rate of evaporation of the Delray boiler can be increased to the maximum desired quantity practically as fast as the stoker and fans can be brought up to the corresponding speeds. The data in Table 3, taken from heat-loss tests on one of the Delray Power House No. 3 boilers, show the effect of thin fires on excess-air and total fan-input quantities. The pressure at the top of the combustion chamber was maintained practically constant, so that the air infiltration quantities through the setting up to that point would be the same. The draft loss through the gas passes of the boiler increased with the excess-air quantities, which undoubtedly resulted in a greater amount of air infiltration through the second and third passes of the setting.

TABLE 3

Test No.	Evaporation, 1000 lb per hr	Excess air, per cent	Drafts: Air pressure under fire, in. of water	Drafts: Top of combustion chamber, in. of water	Drafts: Boiler outlet, in. of water	Total fan input, kw
1.....	250.4	19	1.4	0.07	2.5	141.2
2.....	251.5	25	1.4	0.08	2.6	143.1
3.....	258.0	32	1.2	0.06	3.0	169.3
4.....	252.1	43	1.2	0.05	3.5	213.8

Although the settings have been made reasonably tight, tests show that a considerable portion of the air for combustion throughout the normal operating range does not go through the air preheater. Lower furnace pressures would undoubtedly further increase the air infiltration unless the settings are absolutely tight.

It is the authors' contention that atmospheric pressure is reached in the fuel bed when operating either with balanced draft or a relatively high underpressure in the combustion chamber. With balanced draft, this point is at or near the surface of the fuel bed, while with higher drafts it is probably somewhat below the surface in a fuel bed of equal thickness.

Since the stack action of the hot gases begins at the fuel bed in either case, the only essential difference between the two methods is the fact that with balanced draft the atmospheric point is again reached in the combustion chamber, while with high drafts it is not. Since experience at Delray and other stoker-fired plants of The Detroit Edison Company indicates that operation with high drafts increases the air infiltration and puts more load on the induced-draft fan, the balanced-draft method is employed.

Those changes which were made to the stokers and described in the paper were to correct certain obvious deficiencies, the two most common being the inability of well-trained operators to control the fuel bed properly and the excessive formation of clinkers. Although the original installation of six square-nose pushers resulted in satisfactory combustion at moderate ratings when burning coal with an ash-softening temperature of 2500 F or above, the clinker formations at the stoker front, on the tuyères, and coal and tuyère extension plates were excessive when poorer grades of coal were burned. The clinkers at the front wall and the long clinkers which invariably capped over the tuyères indicated clearly that the coal was coking too low in the retorts. Various pusher-stroke combinations were unsuccessfully tried in an effort to keep the burning fuel off the grates. With six pushers, the stroke reduction required on successive pushers in the retort to obtain the necessary packing and control was such that it would have required exceptionally long top-pusher strokes. Since ignition takes place early on this stoker, it would have been difficult to maintain the proper fuel bed at the stoker front with longer pusher strokes. It was evident that an increased reduction of successive pusher strokes should be obtained by reducing the number of pushers rather than by making changes to obtain longer strokes.

The fuel bed, controlled with long strokes and a large number of pushers, was subjected to excessive agitation. With certain grades of coal which required long strokes, the clinker formation on the tuyères was rapid, and it became difficult, and at times impossible, to prevent the emission of smoke from the stack. It was apparent that fewer pushers would disturb the coal and coke less frequently and the deepened retort would furnish means of packing the coal, so that with proper pusher strokes the desired coal movement and shape of fuel bed could be obtained at all times.

Evidently these predictions were correct, as the entire performance has been improved. Pusher-stroke combinations can readily be found to properly handle coals that were difficult to burn efficiently before the change. Clinker formations at the stoker front are practically eliminated, and the clinkers over the tuyères are reduced in size so that the flow of air is not obstructed. Replacement of internal stoker parts has been reduced, particularly the tuyère side plates, which were formerly burned due to the burning of coal in the retorts. The long beveled pusher at the bottom improved the disposal of clinkers that adhered to the bottom tuyères over the coal and tuyère-plate extensions.

In reply to Mr. Clark's question regarding the cost comparison of different boiler plants, the authors desire to point out that the comparison was made between actual costs of a plant as constructed containing single-ended boilers and a plant containing double-ended boilers. This latter type of boiler used in the comparison is one which has been installed in four earlier plants of The Detroit Edison Company, and considering the many years of experience obtained and the estimators' familiarity and experience with costs applicable to such design, the authors are confident that these cost comparisons represent the true facts as stated in the paper—i.e., that there was no appreciable saving in investment by adoption of the single-ended boiler. All comparisons were made on boilers of the Stirling type. In both cases a high rate of heat release was contemplated, and the furnace was designed accordingly.

The small use of the continuous fuel-burning capacity of the stokers was due entirely to the conditions of the load on the plant. Were conditions such as to require a continuous coal-burning rate in excess of 56 lb per sq ft per hr, special soot-removal equipment would be needed, because, with the average run of fuel, slag would accumulate on the screen tubes during a period of from 10 to 20 hr, requiring removal by hand-lancing. Such procedure is very difficult to accomplish without reducing the rating to a point where operators can do this cleaning effectively. The character of the load on the boilers, however, does not demand continuous steaming at high rates, and during normal day-to-day operation advantage is taken of the low-load periods to do the necessary cleaning with a hand-lance. As far as the stokers are concerned, a continuous coal-burning rate of 75 lb per sq ft per hr or more can be maintained.

During the past three years the market for stoker ash has fallen off to such an extent that whereas the figure of 6.5 cents per ton of coal burned represents the average selling price of stoker ash over a long period of time at or near Detroit, the present price averages only about 1.0 cent per ton. There is reason to believe, however, that as the demand for building materials revives, the price will increase.

The complications and additional costs which would be involved in screening the coal used on the stokers rule out such procedure, as the removal of slag from the tubes is not a costly or difficult operation and is performed at times when the maximum capacity of the boilers is not needed.

Progress in Hydraulics

Hydroelectric Plants

AN IMPORTANT gain during the year has been the fuller realization of the importance of hydro in public-utility systems, as well as the dependence of hydro upon having such load systems to feed into. This emphasizes the interdependence between steam and hydro, and as an evidence of interest in this respect, there should be cited the excellent paper by Irwin and Justin presented at the Semi-Annual Meeting of the A.S.M.E. at Bigwin last June.[1] This paper, although dealing with the economics of hydroelectric development in general, confined itself more or less to two factors subject to evaluation, the energy and capacity values of hydro development, but did not deal extensively with the operating advantages in the way of accommodation to systems and the maintenance of frequency.

A great amount of study is being given by companies that are faced with such problems to making the proper balance in everyday operating practice between the sacrifices that have to be made in steam and hydro in order to secure greater over-all economy. The carrying of peak swings on hydro results in reducing kilowatt-hours of output that could have been generated in operating the plant at a uniform discharge just equal to the river flow. At the same time, this sacrifice is more than made up by the assistance which it renders to the steam system, not only in the saving of investment generally associated with the problem of economics, but also in the daily peak prepared for, as well as the adjustment of the weekly steam schedule to favor particularly the boilers and to keep uneconomical plants off the line as much as possible. This advantage is becoming so important that in the Eastern part of the country many of the large-load centers supplied primarily by steam have important supplements of hydro.

For example, the seaboard cities of New England are receiving energy from the water powers located inland where the rivers are developed at many available sites, Philadelphia derives a large amount of power from Conowingo, while Baltimore likewise receives benefits from Susquehanna plants at Holtwood and Safe Harbor. The trend of development in this way is clearly shown by the interconnections under way for bringing hydro power from upper New York State to New York City and the connection soon to be placed in service between the high-tension line from Safe Harbor to Baltimore and Washington.

In general, it may be said that interconnection is favorable to hydraulic development because it widens the opportunity of making use of the mutual advantages between two sources of power.

The outstanding large development in the West is the Rock Island Plant of the Puget Sound Power and Light Company (Washington Electric Company) on the Columbia River near Wenatchee, Wash. Fig. 1 shows a shop assembly of one of the Rock Island turbines.

The outstanding large development in the East is Safe Harbor, which is unique in many respects, in addition to the installation there of the most powerful Kaplan turbines in the world. Engineering studies were made here and in Europe preliminary to this development. These investigations led to such innovations as the use of double leaf gates, testing by current meters, streamline rack bars, etc.

The contract for these turbines was carried out jointly by the Baldwin-Southwark Corporation, I. P. Morris Division, and by the S. Morgan Smith Company. Fig. 2 shows a shop assembly of one of the Safe Harbor runners.

The official opening of the hydroelectric power station on the

[1] K. McH. Irwin and Joel D. Justin, "Economic Balance Between Steam and Hydro Capacity."

Presented at the session of the Hydraulic Division, Wednesday afternoon, December 7, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Personnel of the Executive Committee of the Hydraulic Division for 1932: Blake R. Van Leer, Chairman; Carroll F. Merriam, Secretary; L. F. Moody, Byron E. White, E. M. Breed, and D. J. McCormack.

Dnieper River, known as Dnieprostroi, took place on October 1. The first unit was put into operation on May 1 last and another four have been finished and gradually tested since then. At the official opening there will be five turbo-generators ready for operation. It will be recalled that the engineering on this project was done by engineers from the United States and that the turbines were built in this country by the Newport News Shipbuilding and Dry Dock Company.

The improvement in the development of propeller-type turbines and the adaptation of the movable-blade idea of Mr. Kaplan into American practice is outstanding. The efficiency characteristic obtainable with this form of construction has opened up a new opportunity for hydro development, in cases not hitherto economically feasible for the Francis turbine or even for the propeller-type turbine with fixed blades.

Practically all of the manufacturers have been interested in attractive variations of the movable-blade turbines. Some of these have blades adjusted by hand from time to time, some propose regulating entirely by the movement of the blades, thus eliminating the usual turbine gates, and another would have the

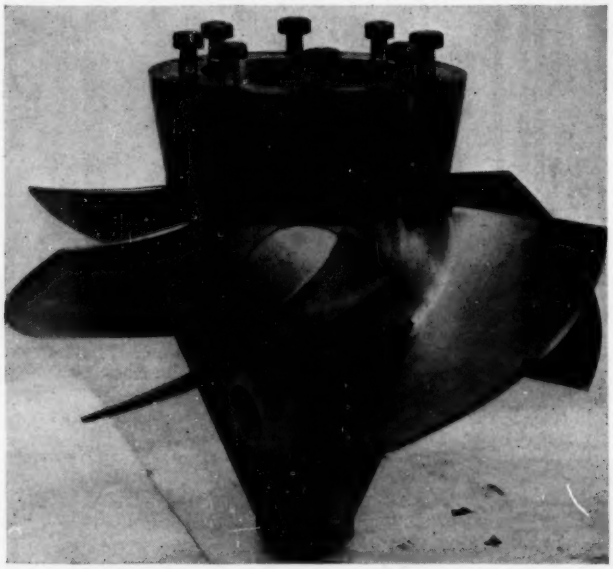

FIG. 3 MODEL OF ADJUSTABLE-BLADE TURBINE IN WHICH THE POSITION OF THE BLADES IS CONTROLLED BY THE FLOW OF THE WATER THROUGH THE TURBINE
(Photograph by courtesy of Newport News Shipbuilding & Dry Dock Company.)

blades adjusted entirely by the flow of the water through the turbine. A model of this last type is shown in Fig. 3.

Although little progress has been made during the year in pumped storage plants, some effort has been devoted to investigating their possibilities and to experimenting with the use of hydraulic prime movers as pumps, thus deriving the benefits of pumped storage without the necessary cost of providing separate pumps, reservoirs, etc. (See F. A. Allner's paper, A.I.E.E. Convention, Baltimore, October 12, 1932.)

There is increasing appreciation that the incremental cost per kilowatt of hydro development compares very favorably with that of steam; and so with the growth of power systems, and increasing sharpness of the peaks that must be carried as a part of the duty of a public utility to its customers, we may look to hydro as a means of securing a limited amount of peak capacity.

In order that hydro may serve to supplement steam to the best advantage, it should be able to perform the important function of governing. Large interconnected systems in the East are looking to the low-head run-of-river plants, especially those having comparatively short water passages, to control frequency. Considerable improvement has taken place in design of the governing systems, especially in the arrangement of the component parts. One plan is to connect the governors of adjacent units in pairs in order to combine the advantages of the central pumping system with those of the unit system. Fig. 4 shows a

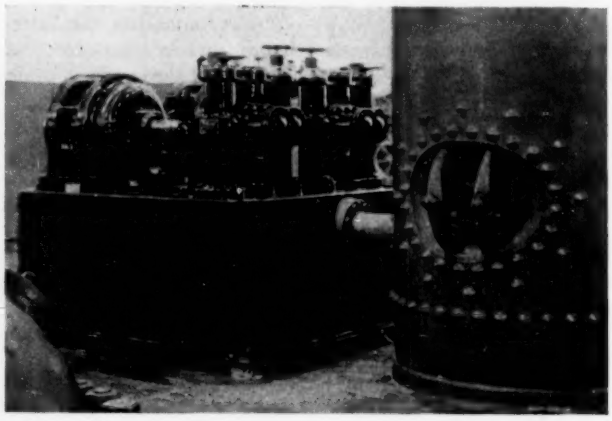

FIG. 4 COMPACT ARRANGEMENT OF GOVERNOR PUMPS, SUMP TANK, AND ACCUMULATOR
(Photograph by courtesy of Woodward Governor Company.)

compact arrangement of pump, sump tank, and accumulator to reduce the amount of piping necessary.

The introduction of the propeller turbine in general and the Kaplan wheel in particular has opened up new possibilities in the development of low heads which would be impossible with wheels of lower specific speed. It has been pointed out in a paper presented before The American Society of Mechanical Engineers at its Annual Meeting, December 5, 1932, by Prof. W. Spannhake, that in order to take advantage of these possibilities it will be necessary to pay special attention to details of design.

Kaplan wheels are particularly adapted to carry swinging loads without serious loss in efficiency. In the future these wheels will possibly be operated with an effective speed drop much less than has hitherto been thought possible without a sacrifice in stability of the unit while operating in parallel with others. It is also possible through the governor to give the unit very desirable operating characteristics.

Considerable attention has been given to the operation of hydro units as synchronous condensers. Such practices increase the usefulness of a turbine when operating on a large system.

With the advent of the Kaplan unit it has been very important to find some method of securing a comparative measure of the amount of water used. For this purpose it is not necessary to know the absolute quantity of water as long as a comparative measure may be found to indicate on an arbitrary scale the economy secured. There are several methods for doing this, but recent experiments have shown that highly satisfactory results have been obtained by observing the pressure differences at various points in the wheel casing.

In the field of testing by actual water measurement a great deal of progressive work has been done with current meters, using a method which is an adaptation of that commonly used in Europe.

As a result of experience, improvement in technique has been made which allows the field and office work to be reduced.

Certain power companies have reported very gratifying results from long-time forecasting of water supply by cyclic analysis. These companies are located where conditions are probably as

favorable as in any part of the country, and although their success cannot be taken as proof that the method is generally applicable, it does show the possibility of solving the mystery of cyclic variations in meteorological phenomena and that success may possibly be attained in other localities when the confusing influences are correctly analyzed.

Gratifying results have been secured from model testing and the development of new runner designs based on experimentation. During the year a unit has been installed, breaking the world's record for high efficiency of a unit tested in place. This success was the result of the surprisingly high efficiency attained by the commercial-size model tested in the Holyoke flume.

Fig. 5 shows the shop assembly of one of the three units in this plant.

A laboratory designed especially for studying cavitation has been exceedingly busy deriving the characteristics of runners and studying the influences that are conducive to cavitation. At the same time there is being conducted at the Massachusetts Institute of Technology an extensive series of research tests to determine the fundamental principles that govern the phenomenon. Attention is being given especially to the pressure distribution in the zone of cavitation and the influence of cavitation on various metals and protective coatings. The formation of the cavitation bubbles and their collapse is being studied by means of spark photography.

Particular attention is being given to two important subjects: the economical operation of plants and simplification of power-plant design. Material is being collected from companies that are active in promoting not only efficiency of operation, but also saving in operating and maintenance expenses and in the better use of available water supply. Another group is gathering a large amount of information and suggestions regarding the means that have been taken in recent plants for securing more economical design, either by outright reduction in first cost or by savings to be effected as the result of better design. The material collected so far is evidence of the activities which plant designers have shown in their endeavor to secure a more

(Photograph by courtesy of Ingersoll-Rand Company.)

economical development of hydro resources. It is encouraging to note that in a plant recently built (Eagle Pass) it was claimed that attention to architectural details had not added appreciably to the cost.

Hydroelectric engineers have shown a keen interest in securing better and more durable concrete for hydraulic structures, and as a result we can look to better understanding of the factors which are essential for building durable structures.

Progress on the Hoover Dam was recorded early in November, when the Colorado River was diverted into the bypass tunnels in the canyon walls, this marking the completion of the first stage of the work, said to be a full year ahead of schedule.

Interest was also aroused by the announcement (see *Power*, August, 1932, p. 101) that the contract had been let for 55,000 tons of steel-plate work for four main headers, 30 ft in inside

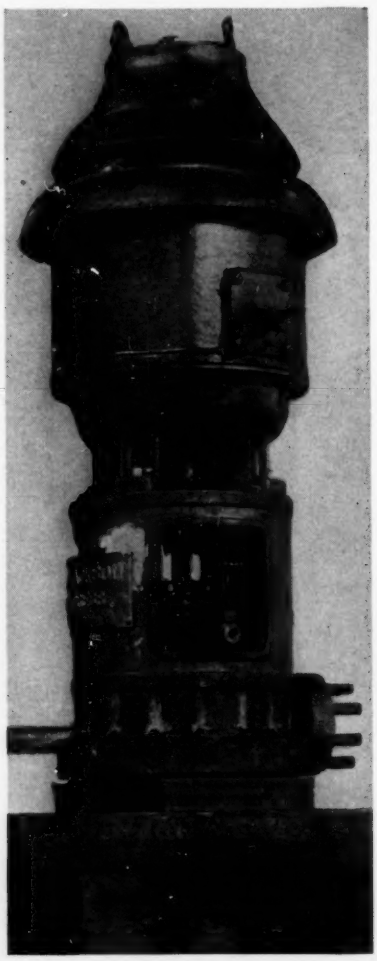

FIG. 8 ONE OF TWO HYDROPRESS PUMPS INSTALLED AT THE GRAND CANYON
(Photograph by courtesy of Byron Jackson Company.)

diameter, each one of which will feed four 13-ft penstock outlets, which will carry the water to the 16 turbines. The plate is to be welded to conform to the current rules for the fusion process of welding, Class 1, A.S.M.E. Boiler Construction Code for Unified Pressure Vessels.

A most important contract was received by the S. Morgan Smith Company from the United States War Department for eleven roller gates to be installed on the Mississippi River for flood control. These gates will have a damming width of 100

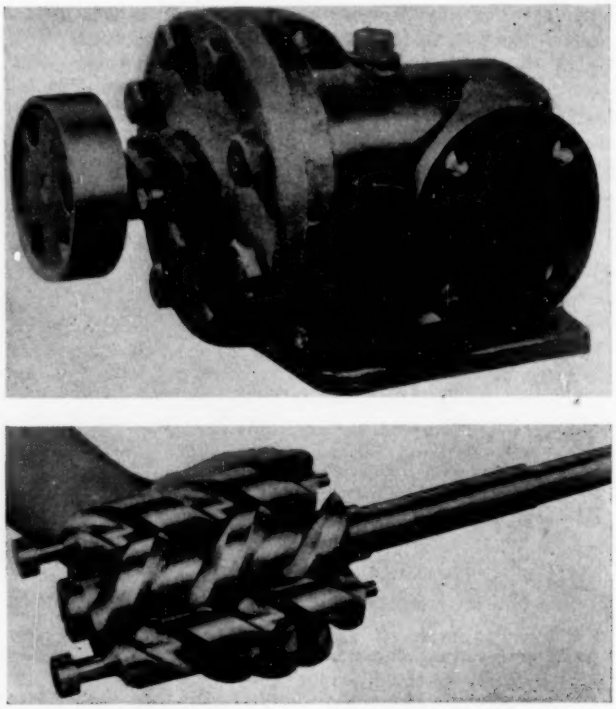

FIG. 9 ASSEMBLED UNIT AND ROTORS OF A POSITIVE DISPLACEMENT PUMP
(Photograph by courtesy of DeLaval Steam Turbine Company.)

ft and the largest of them is 26 ft high. Fig. 6 shows one of these gates before installation.

PUMPS

As in the case of water-power development, there has been a limited activity in the development of pumps and pumping plants. There have been a number of installations with new features of design and some having special interest to the technical man.

Some noteworthy advances in the development of high-head centrifugal pumps have been made. Hot-oil charging pumps up to 4800-ft head in one case and up to 7200-ft head in two cases, with efficiencies reaching 70 per cent, have been reported. A multi-stage high-pressure hot-oil pump has been built in various sizes and stages which develop pressures up to 1500 lb when handling 100 to 800 gal per min at temperatures ranging up to 750 F. Such a pump is illustrated in Fig. 7.

Further encroachment on the reciprocating-pump field by centrifugal pumps is shown by units furnished for the Grand Canyon, where they are pumping 90 gal against a 3400-ft head from the bottom of the canyon to the top. One of these pumps is shown in Fig. 8.

In the last year practically every manufacturer of electric motors has completed an extended line of 3600-rpm motors, which include horsepowers up to and including 200. With these motors now available, it has made the introduction of high-speed single-stage pumps possible for heads in excess of 650 ft.

It has become generally recognized that adequate absolute pressure on the intake side of a centrifugal pump is necessary for satisfactory operation. Studies and experiments have been made of the problem both here and abroad and have served to establish the fact that attainable limits depend upon, and in fact are fixed by, the specific speed of the pump. It seems impractical at this time to predict from any mathematical analysis at what absolute suction heads cavitation begins. A group of manufacturers of centrifugal pumps has agreed to accept certain limita-

tions in specific speed which will have an adequate margin of safety, based on experience. Charts have been developed which show the upper limit of specific speeds for double-suction, single-stage centrifugal pumps at a normal water temperature of 80 F and operating under heads from 45 to 350 ft. For heads greater than 350 ft, considerably more experience will be needed, even though there are a number of installations in actual operation with heads as high as 1000 ft per stage.

A new rotary-type positive-displacement pump has been developed. The power rotor has a convex tooth contour, which fits the concave contour of the idling rotors, providing an almost fluid-tight closure. The idling rotors are driven by fluid pressure, making pilot gears and bearings unnecessary and requiring only one stuffing box. High speeds for direct connection to motors or turbines, pressures up to 4000 lb, and high efficiencies are advantages claimed for this pump, illustrated in Fig. 9.

bed loads. Work has already been started on these problems.

Experimental seamless steel and copper tubing in 4 in. and 6 in. diameters has been obtained for the pipe-bend project, and various types of joints are being studied with a view to causing the least possible disturbance of flow due to the joints.

Other research problems proposed for study in the National Hydraulic Laboratory are: Coefficients for orifices and weirs of all types; the hydraulic jump; flow around bends in pipes and channels; laws of movement of detritus; loss in pipe lines and fittings; wave phenomena; cavitation; scale effects, etc. Model tests have been proposed on flow in chutes and transition sections; erosion below dams; studies of siphon spillways; entrainment of air in tunnels; backwater due to various structures; silting of canals, etc.

Tulane University has established a hydraulic laboratory for the study of fundamental hydraulics.

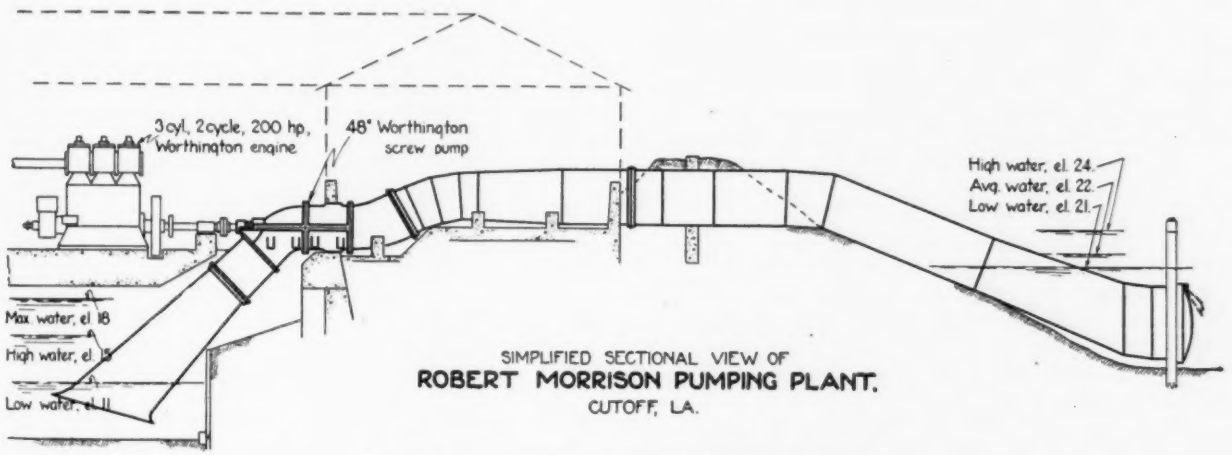

FIG. 10 INSTALLATION OF LOW-HEAD PROPELLER PUMP
(Drawing by courtesy of Worthington Pump & Machinery Corporation.)

In the low-head field (and by that is meant heads below 45 ft) a number of installations of the propeller-type pump have been made. Their application has not become so general, however, as to cover all the possible variations in pumping conditions for which they are said to be suitable. Experimental research is proceeding, but as an example, practical operating data are not yet available to establish the relationship between absolute suction pressure and specific speed. A 48-in. propeller pump under test delivered 52,400 gpm against a dynamic head of 9.8 ft with an efficiency of 78 per cent. Fig. 10 shows the installation.

HYDRAULIC LABORATORIES AND RESEARCH

The outstanding item of interest in this field is the announcement of the completion of the National Hydraulic Laboratory at the Bureau of Standards in Washington, D. C., and the initiation of the first experimental projects. The building of this laboratory was completed in March of this year, and the installation of equipment began immediately. The laboratory has been described in *Mechanical Engineering* and in the technical press.

About twenty research problems have been submitted to the laboratory by several bureaus of the Federal Government for study at the earliest possible date. These include an investigation of the loss of head at bends in large pipe lines, the study of means for preventing the silting of an irrigation reservoir, methods and appliances for measuring the depths of swift and deep rivers, the effect of turbulence on current meter ratings, study of deep-well current meters, the velocities necessary to transport sand particles of various sizes in streams, and a study of the

The new University of Tennessee Hydraulic Laboratory features a complete hydroelectric unit assembly.

Construction work has been started on a new hydraulic laboratory for the Newport News Shipbuilding and Dry Dock Company. It is expected that this laboratory will be ready for operation in March, 1933. All modern facilities for testing turbine and pump models and component parts of hydraulic-power installations are provided for. Provisions are also being made in this laboratory for the study of cavitation and pitting.

The laboratories of the various hydraulic machinery and equipment companies have been carrying on experimentation for the improvement of their specific lines, and considerable progress as a whole can be indicated. One line of laboratory experiment is on the development of reversible pump-turbine units which may operate efficiently either as a pump or as a turbine. One model reported suited to high heads developed 85 per cent as a pump and 89 per cent as a turbine. Another line of experimentation is in the development of propeller-type pumps. An axial-flow propeller pump with centrifugal discharge has shown good efficiency and high specific speeds. One company has been developing a type of adjustable-propeller runner for turbines in which the vanes are adjusted by the flow of water through the turbines.

Since research operations are expensive in money as well as in time, the possibilities of carrying on any worth-while studies are limited very materially by the reduced income from production. However, this survey of activity shows that during this period considerable development and experimental work is being carried on to place the hydraulic industries in a better position to take advantage of increased business activity in the future.

HYD-55-2

A Study of the Data on the Flow of Fluids in Pipes

By EMORY KEMLER,[1] PITTSBURGH, PA.

It was not until 1883, when Reynolds by dimensional analysis developed the equations for dimensional homogeneity and dynamic similarity, that any scientific basis for analyzing the experimental data on the flow of fluids was available. In view of the fact that only a small part of the experimental work previous to that of Stanton and Pannell has been reduced to Reynolds' dimensional basis, it was deemed desirable to undertake the present investigation in order to get a more complete knowledge of the flow problem, and in it an attempt was made to obtain all the data available on flow in pipes under pressure.

Some of the more important conclusions to be drawn from the data presented are:

1 The friction factor is independent of the fluid flowing for the same values of the Reynolds number *R*.

2 The friction factor for drawn brass pipe varies only ± 5 per cent from an average value and is substantially independent of the pipe size and fluid flowing for the same value of *R* within the range encountered in practice.

3 The friction factor for new steel pipe varies with the size, and varies about ± 10 per cent from an average value.

4 The data on used and artificially roughened pipes show that if the roughness is not large enough to cause contraction and enlargement losses, the friction factor never exceeds the value 0.054.

5 The mean hydraulic radius can be safely used as a criterion only in the turbulent region.

6 Special care should be taken in the selection or determination of the diameter.

I—INTRODUCTION

IT WAS not until 1883, when Reynolds[2] by dimensional analysis developed the equations for dimensional homogeneity and dynamic similarity, that any scientific basis for analyzing the experimental data on the flow of fluids was available. Little attention was given this work by engineers until the last few years. The early experimenters, starting with Couplet in 1732,[3] attempted to develop empirical formulas to fit their experimental results. The result was that, while formulas were developed that fitted the data, they were applicable only to a particular pipe size within a given velocity range, and only to one fluid. The work of Stanton and Pannell[4] in 1914 on the flow of fluids through smooth pipes was the first real advance in the application of the method of dimensional analysis to fluid-friction problems which arise in engineering practice. Their experiments on compressible and incompressible fluids showed that this method of analysis was practically as well as theoretically correct. Since that time there have appeared a number of researches on the flow of fluids which have demonstrated that this method of handling the problem is satisfactory.

In view of the fact that only a small part of the experimental work previous to that of Stanton and Pannell has been reduced to Reynolds' dimensional basis, it was deemed desirable to undertake the present investigation in order to get a more complete knowledge of the flow problem.

II—TYPES OF FLUID FLOW

Reynolds[5] found from his experiments on the flow of fluids that there are two types of fluid motion. These experiments were made by drawing clear water through a transparent tube and admitting a very small stream of colored fluid near the entrance to the tube. When the velocity was low the stream of colored fluid extended through the tube in a straight line without mixing with the water. As the velocity was increased it finally reached a value at which the colored stream would mix with the surrounding water and the tube would appear to be filled with a colored liquid.

The first of these types of flow is called streamline or viscous flow, and, as the motion of the fluid particles is definitely known, the problem of flow for this case can be treated mathematically. The second type is called turbulent or sinuous flow. In this type of flow, eddies are present, and, since the motion of the individual particles is not known, the problem of flow in this case must be studied experimentally. The principle of dimensional homogeneity offers the method of approach to the study of the turbulent-flow problem.

III—DIMENSIONAL HOMOGENEITY

The principle of dimensional homogeneity[6] states that in any complete physical equation all equal terms must have the same dimensions. It can be shown by this principle that, since only the diameter of the pipe, the velocity of flow, the density of the fluid, and the viscosity affect the loss of head per unit length, we can express the loss of head by

$$\Delta p = \rho \Delta h = \frac{f l v^2 \rho}{2gD} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

provided f, the friction factor, is a dimensionless quantity. Reynolds showed that for this to be true it must take the form

$$f = \phi\left(\frac{Dv\rho}{\mu}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

that is, f must be some function of $Dv\rho/\mu$. The form of this function must be determined experimentally for turbulent flow. Hereinafter the term $Dv\rho/\mu$ will be called Reynolds' number and will be designated by R.

List of Symbols

D = diameter in feet
v = velocity in feet per second
ρ = density in lb per cu ft
μ = absolute viscosity in ft-lb-sec units
ν = kinematic viscosity in ft-lb-sec units
l = length of pipe in feet
g = 32.2 = acceleration of gravity
f = friction factor
R = Reynolds' number
Δp = drop in pressure in lb per sq ft
Δh = loss of head in feet of liquid
W = pounds of fluid per second
V = volume
m = mean hydraulic radius.

IV—THE CRITICAL REYNOLDS NUMBER

The value of Reynolds' number at which the type of flow changes from streamline to turbulent flow or vice versa, is called the critical Reynolds number. This number is not well defined and may vary over a considerable range. In this unstable range of R the projected friction factor for streamline flow falls below the value for turbulent flow. Because of this fact, it is the minimum value of Reynolds' number at which turbulent flow can exist under normal conditions in which we are interested, since this value represents the maximum value of f that will be found in practice.

Schiller[7] concluded from his experimental work on the problem of turbulent flow that, for every Reynolds' number above 1160, a definite amount of disturbance is necessary to produce turbulence. The higher the Reynolds number, the less the disturbance necessary. Below the critical number R = 1160, viscous flow is stable against all disturbances. This value will be called the absolute critical Reynolds number for straight circular pipes. There no turbulent flow is possible; any eddies occurring will, after a sufficient distance, always disappear.

Hopf in the "Handbuch der Physik"[8] gives a review of the work done on determining the value of the critical Reynolds number and says that 2000 is a minimum value at which turbulence occurs under conditions similar to those met in practice. Streamline flow may continue at higher values, but turbulent flow cannot continue below this value except under the most favorable conditions. The various experimenters have found that under ordinary conditions the critical value varies from approximately 2000 to 3000. The region between these two values is an unstable one and the value of the friction factor depends upon how this region is approached. For instance, Ekman[9] was able to maintain streamline flow up to a Reynolds number of 25,500 by using smooth tubes and taking precautions to eliminate any disturbances at the entrance. At such values of R any slight disturbance would immediately change the type of flow; the phenomenon being somewhat similar to supersaturation or to undercooling.

It is interesting to note that in the case of curved or inclined pipes the critical Reynolds number is reduced below 1160, which has always been considered as the minimum value. Gibson and Grindley[10] obtained a critical number of 130 in experiments on the flow of air through a brass tube 0.32 cm in diameter coiled around a drum 36 cm in diameter. Jeffrey[11] also found that turbulent flow of water in an inclined rectangular section starts at a much smaller number than in a straight pipe. Carothers[12] obtained a critical Reynolds number of 200 for oil flowing in jointed pipes, and Davies and White[13] found that R = 1440 was the critical number for rectangular pipes. Schiller[7] quotes results of Ruches and Sorkau, who, respectively, found R = 400 and R = 430, as the critical number for glass capillary tubes. This shows that the critical number varies widely with conditions, and that any maximum, average, or minimum value that is set forth must be qualified. A more detailed discussion of the problem is given by Hopf in the "Handbuch der Physik"[8] and by Bateman[14] in the National Research Council's book on hydrodynamics.

Experimental data show that in straight pipes the transition from streamline to turbulent flow takes place about as shown in Fig. 1. Gibson[15] states that at low velocities the stabilizing effect

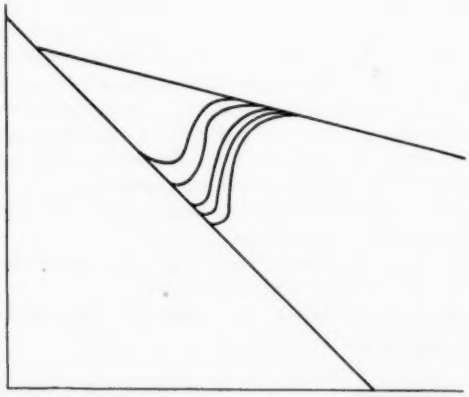

Fig. 1 Some Typical Curves in the Critical Region
(From Prandtl and Tietjens' "Hydro- und Aeromechanik," vol. 2.)

of viscosity prevents any tendency to deviate from streamline motion, such as may be produced by roughness which tends to set up eddies in the stream. It is probable that when the change is from the streamline to the turbulent region, the forces setting up eddies are not strong enough to send the entire system into turbulence, there being some damping of the eddies until some higher velocity is reached when the stabilizing effect of the viscosity has little to do with the flow.

However, if the change is from the turbulent to the streamline regions, the turbulence may persist until a value of 2000 or thereabouts is reached before the change to laminar flow takes place. In this case the damping effect of viscosity is not enough to stop any of the eddies. The suddenness with which this change takes place is probably dependent upon the roughness of the pipes, since

this could have a decided effect on the starting of eddies. It will also depend upon the viscous friction which is the cause of the damping effect. In order to get results that will agree with average conditions it is considered here that the streamline region exists to a value of $R = 2000$, at which value there is assumed to be a sudden change to turbulent flow.

The production of turbulence and instability of laminar flow has recently been discussed by Tollmien.[16] He shows that turbulence can only originate because of the instability of laminar flow, and that the critical Reynolds number depends largely upon the disturbances occurring.

V—STREAMLINE FLOW

As stated earlier, streamline flow can be treated mathematically since the flow satisfies the hydrodynamical equation of Navier-Stokes. In this case the pressure drop results from the shearing stresses necessary to move the particles relative to each other, or it may be considered as being caused by the viscosity of the fluid. The equation for pressure drop can be derived on this basis and is given by

$$\Delta p = \frac{64\,\mu l v}{2\,g D^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Equation [1] will also apply to viscous flow provided f is a function of R. It has been found for streamline flow that $f = 64/R$. Substituting this value for f in Equation [1], the result is the same as that given by Equation [3]. The pressure drop for flow in straight pipes can then be calculated by Equation [3] provided R does not exceed 2000 and the pipe is circular in cross-section. Flow in non-circular sections will be discussed later.

[16] Tollmien, "The Present State of the Turbulence Problem." Paper before Pacific Coast Aero Meeting, June, 1932.

VI—ANALYSES OF TURBULENT-FLOW DATA

1 Method of Analyzing Data

In summarizing the data on turbulent flow for pipes, the original or published data were recalculated and analyzed on the basis of dimensional homogeneity. The data of each experimenter on a particular pipe size were recalculated and then plotted. An average curve for the particular pipe size was then selected. This average curve has been put on the summary drawing to serve as a permanent record and for the selection of a final average for a particular kind and size of pipe. Each curve on the summary drawings is marked with a letter and number. The letter refers to the experimenter (the letter used for each experimenter being given in the table of references), and the number to the inside diameter of the pipe in inches. Riveted steel, wood, and cement pipes are treated differently, as explained in the discussion of each.

In many cases data on the temperature of the water or gas were not given. A value of the temperature was then assumed in order to select a value of the viscosity. The assumption of the temperature or viscosity does not change the value of f since it is calculated from Equation [1]. The viscosity does, however, enter into R and defines the relative location of f. Therefore any error made in selecting the viscosity merely moves the friction curve parallel to the R-axis. Because of the general flatness of the friction curve in the turbulent region, a considerable change of μ does not change the position of the curve enough to alter the results to any appreciable extent.

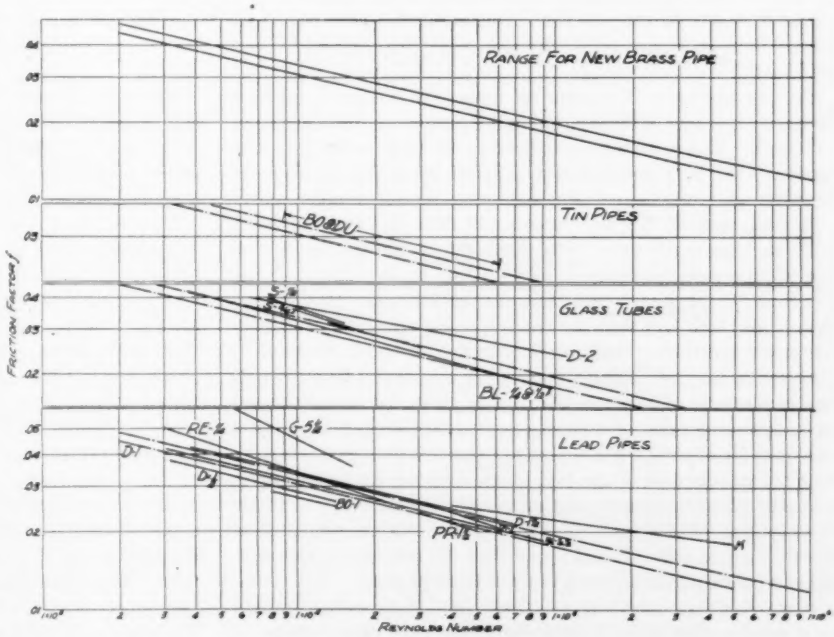

FIG. 2 FLOW IN SMOOTH PIPES

The fact that there is no slip at the boundary or surface of the pipe in either streamline or turbulent flow makes it seem reasonable that the friction factor at the absolute critical Reynolds number should be independent of the pipe size. On this basis at a Reynolds number of 1160 the friction factor should be independent of the pipe size regardless of its roughness provided the

diameter used is the one to make the friction curve coincide with Poisueille's law in the viscous region. This then gives one point for comparing the friction curve for various sizes of steel pipe as well as rough pipes, and its significance will be discussed in detail later.

The curves for flow in smooth pipes are taken as the basis upon which the averages for rough pipe were selected. Considering the large amount of data and the consistency of the friction factor, there is no reason why values of friction factor for rough pipe should ever fall below the values for smooth pipes except in the event of experimental errors. Therefore no data falling below the values for smooth pipe were given any consideration in selecting an average. In the analysis of the data, each type of pipe is considered separately and the various sizes of steel pipes are analyzed separately.

2 Smooth Pipes (Fig. 2 and Table 1)

The flow in smooth pipes offers a starting point for the study of the general turbulent-flow problem since they will have the lowest friction factor and will therefore determine the minimum value of friction factor obtainable. Smooth pipes are closely approximated by good commercial drawn brass pipe. Smooth lead, glass, and tin pipes also give results near those of brass pipe. Fortunately a considerable amount of experimental work has been done on this kind of pipe, so any conclusions that can be drawn will be well substantiated by experimental evidence. A few summaries have been made by other investigators of the work on smooth pipes, but none of these has taken all the data available for use in their analysis. In the following summary all the experimental data that have been published were reduced to the basis made available by Reynolds.

(*a*) *Brass Pipe.* The tests on brass pipe analyzed numbers between 1500 and 2000 and represent pipe sizes from 0.107 in. to 5 in. in diameter, using air, water, and brine as fluids. The summary of the sources of test data on brass pipe is given in Table 1.

In analyzing the immense amount of data on brass pipe each individual series of tests by a particular experimenter on one size of pipe were recalculated and plotted, using f and R as the coordinates. It was found that the experiments gave values that agreed well and that the friction factor was independent of the pipe diameter for the pipe sizes tested for equal values of R. The results for the different fluids were also found to be in perfect agreement. Therefore with brass pipes the friction factor for a particular value of R can be used regardless of the pipe size and fluid flowing. In the analysis of the test data it was impossible to reproduce all of the data in one drawing since so many of the tests gave identical results, and it became necessary to study the problem by determining the boundary within which all of the data would fall. It was found that the two curves shown in Fig. 2 would contain all but a few scattered points.

It was felt that even with relatively smooth pipes there would be a small variation in friction factor for each pipe because of slight variations in the pipe surface. By representing the friction factor as falling within a certain range, as was done in this case, the results would more nearly represent the actual conditions than by using a single average line. The lower curve represents a value of the friction factor about 10 per cent lower than the upper or maximum value. The range of friction factor for smooth pipes can be considered as varying by ± 5 per cent from an average curve. Considering the nature of turbulent flow and the variations in commercial pipe, this is rather consistent from an engineering standpoint.

There are no experimental data on flow at very high Reynolds' numbers for smooth pipe. In order to get some idea as to how the friction factor may behave at these high values of R, we must depend upon the present theories of turbulence. Schiller[7] states that even the technically smooth pipes become hydrodynamically rough at high Reynolds' numbers. The equation $\Delta = 8D/fR$ which is derived by Schiller[7] gives the approximate boundary-layer thickness (Δ = thickness of boundary layer in inches if D is taken in inches). When the boundary layer becomes the same thickness as the roughness projections, complete turbulent flow takes place. While this gives a plausible explanation as to why the friction factor should reach a minimum value, it does not explain why with complete turbulence we should find the friction factor varying from 0.54 to very small values depending upon the roughness. For the explanation of this we can revert to Prandtl's theory of turbulence. In his theory he introduces a distance, l, called the mixing length, which is a term analogous to the idea of mean free path used in the kinetic theory of gases. According to Prandtl, a particle travels a distance l perpendicular to the direction of mass flow before it loses any momentum. The momentum loss is then directly dependent on l. Von Kármán[17] has shown that this mixing length is directly proportional to the roughness projection. This would mean that with any given roughness projection the mixing length is fixed, hence the energy losses are fixed and the value of f, which depends upon the energy losses, is fixed and varies directly with the roughness projection.

The foregoing discussion is not to be taken as a rigorous proof since the explanations given are very much simplified, and the theory of turbulent flow has not been placed on a final mathematical basis. However, while based upon the present theories, the discussion is intended only to give a plausible explanation which will be helpful in interpreting some of the experimental data.

(*b*) *Glass Tubes.* For the remaining types of smooth pipes the average curve for the individual experimenter and pipe size is given on the graph. Each curve is labeled by a letter which refers to the experimenter and by a number which is the inside diameter of the pipe in inches.

The results of Blasius for glass tubes fall within the values for smooth pipes and indicate that the values for smooth pipe can be used for calculating pressure losses provided there is no appreciable variation in the diameter. The test values by Darcy are high, the reasons being that the tubes vary in diameter and that these variations in diameter cause an increase in energy losses because the fluid is speeded up and slowed down as it passes along the tube. The test results obtained by Smith seem to be high, and the reason may be because of variations in actual size from that used in the computations and in a failure to correct for entrance losses which are a considerable factor in short tubes with sharp entrances.

(*c*) *Lead Pipe.* If the lead pipe is drawn, the surfaces will be smooth and the values will correspond with those of smooth pipe. The results in general show clearly that the values for lead pipes correspond with those for the smooth or brass pipe. The test by Couplet was on a pipe made of rolled lead that had several bends. This resulted in high energy losses, and consequently the apparent friction factor is much higher. The tests by Kester were on pipes with couplings and would therefore be expected to show a higher apparent friction factor than a uniform pipe.

(*d*) *Tin Pipe.* The results for the tests on tin pipe fall on the upper line for smooth pipes. Since there are no data on the method by which the pipes were made or on their condition, the results are not entirely conclusive, but obviously since the method of manufacture and the surface character of the material are

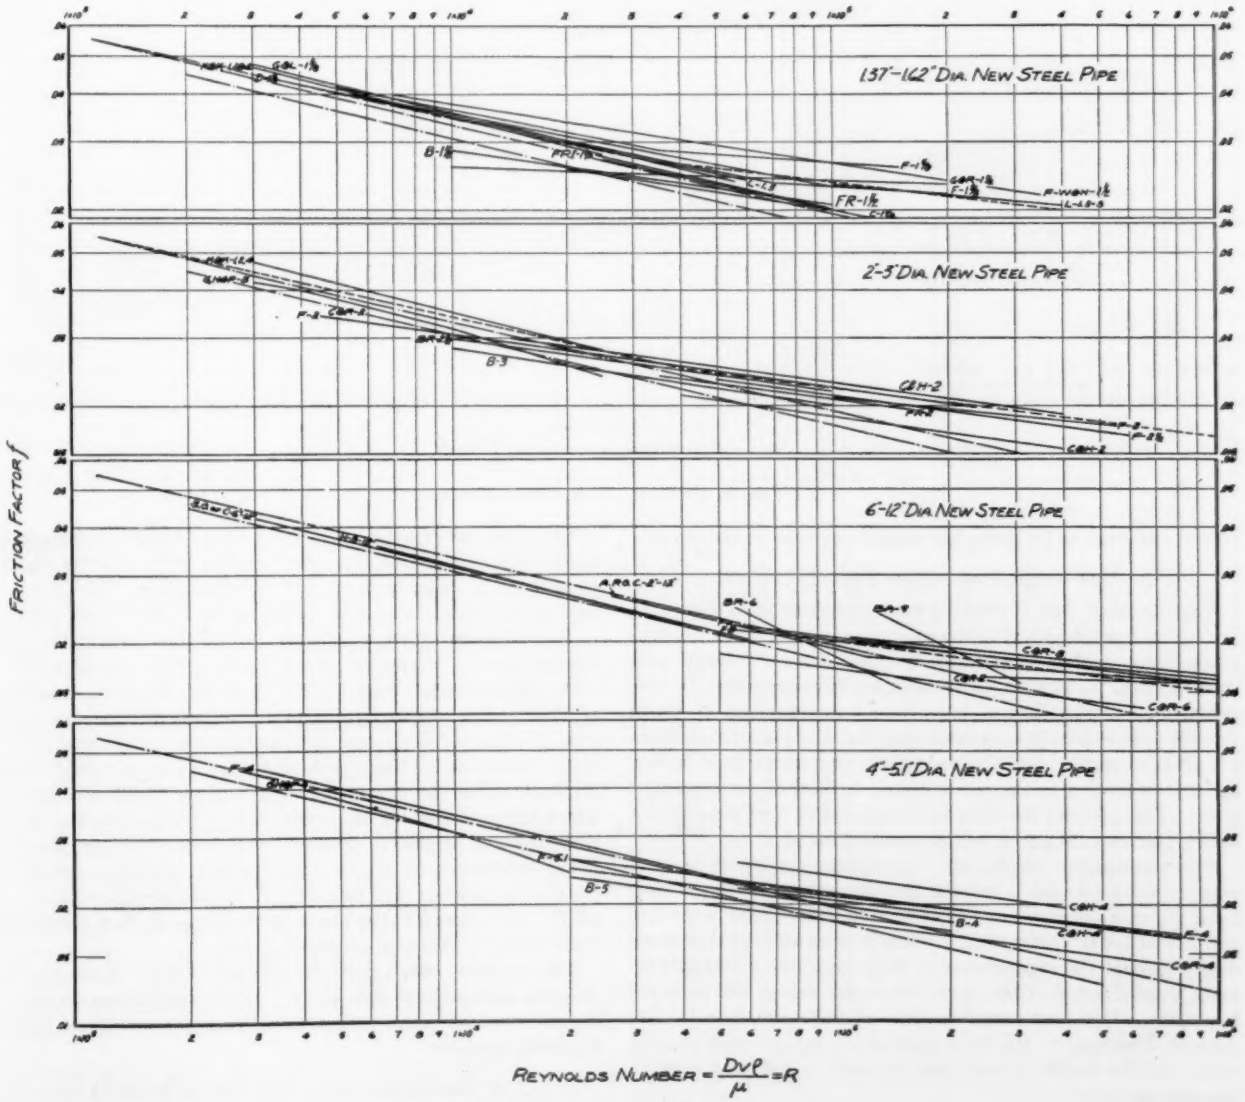

FIG. 3 FLOW IN NEW STEEL PIPES

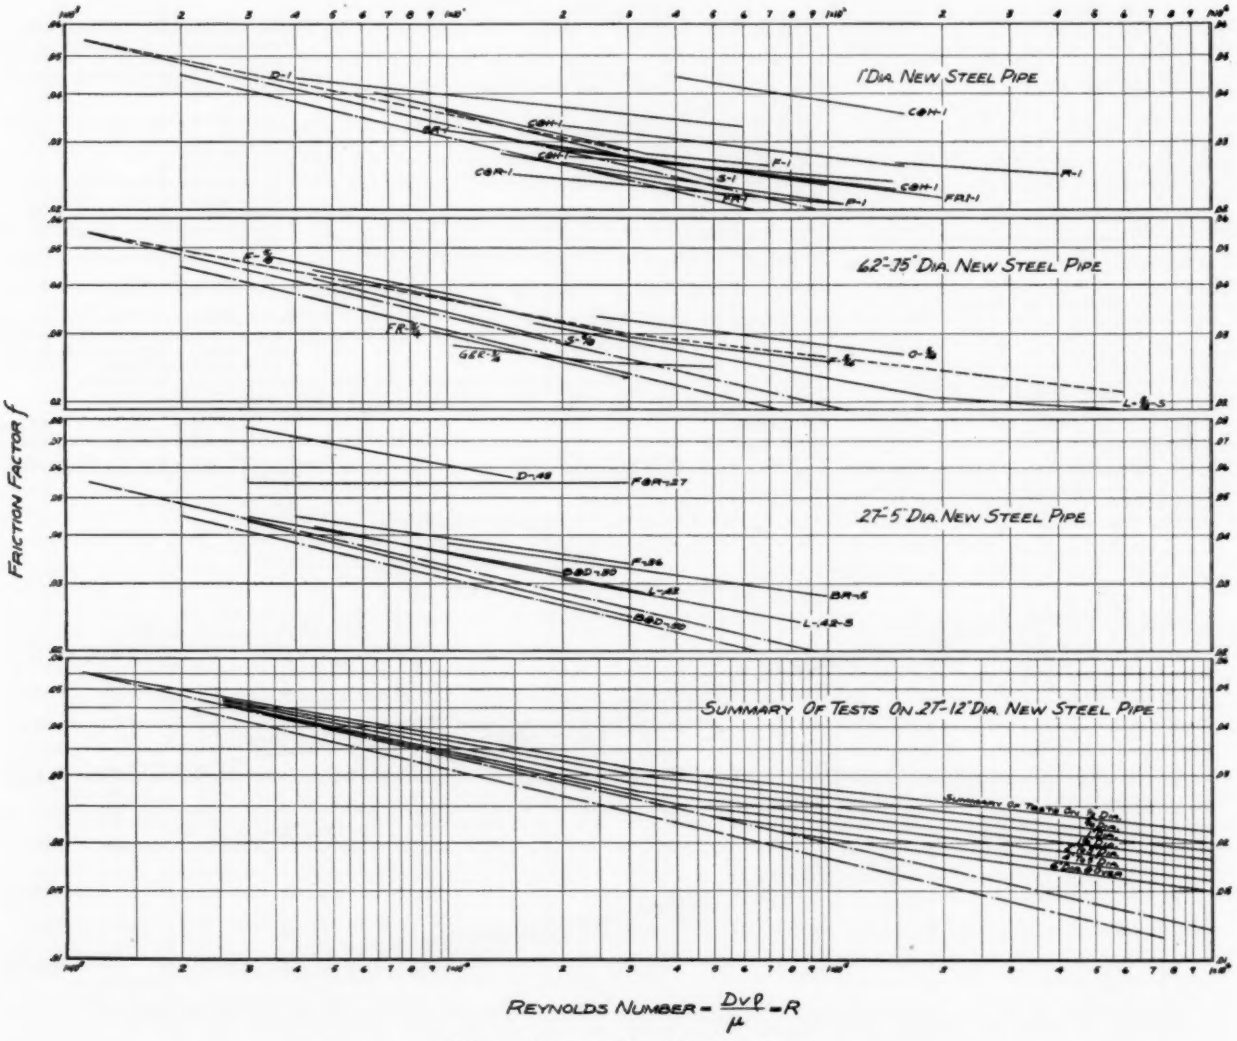

Fig. 4 Flow in New Steel Pipes

almost the same as for brass, the results ought to be the same.

3 New Steel Pipes (Figs. 3 and 4, Table 2)

The turbulent flow of fluids in steel pipes has never been subjected to a scientifically planned study because most investigators were unable to correlate the data for the various pipe sizes or their data with those of other investigators. In this analysis all of the data of independent investigators of which records were available have been compiled and studied. Curves are grouped on the basis of actual inside pipe diameter in inches, and not according to the conventional method of denoting pipe sizes. This permits the data to be applied to heavy and extra heavy pipe and tubing as well as to standard pipe.

The summarized results are surprisingly consistent in that extreme values do not in general vary more than ± 10 per cent from the average curve at higher values of Reynolds' numbers, and less at lower values of R. When it is considered that these data represent the experiments of 26 independent investigations made over a period of 80 years, the results are all the more remarkable. The most complete series of tests are those by Dr. John R. Freeman.[18] His tests covered the entire range of pipe sizes, and the results in each case are seen to fall very close to the average curve.

[18] Mills, "Flow of Water in Pipes."

The oldest set of tests are those by Darcy, which were made in 1852. The $^1/_2$-in. and 1-in. sizes show a friction factor higher than those in other tests on corresponding sizes. The description of the pipes states that the diameter varied as much as 18 per cent for these sizes, which accounts for their apparently high friction factor. His results on the $1^1/_2$-in. size are consistent with other experimental results. The tests by Lander on steam (L-.42-S) and on water (L-.42) form a continuous curve and show that the flow of dry steam practically follows the dimensional law. The tests by Feely and Riggle on $^1/_8$-in. standard black pipe also show the curve for water and air to be continuous. These tests were made on a pipe ordered from stock and show that this size of pipe is relatively very rough. A test using a heavy lubricating oil showed that the measured pipe size made the friction curve for low Reynolds' numbers follow the curve $f = 64/R$, which gives a better check on the diameter than measuring the volume by filling the pipe with water.

The summary curve gives the selected average values for the different sizes of new steel pipes. *The extreme values do not in general vary more than ±10 per cent from the average at higher Reynolds' numbers.*

4 Galvanized Iron Pipe (Fig. 5, Table 3)

Galvanized iron pipe, because of the method of manufacture

and the variation in roughness, is to be expected to give varied results. The general range is considerably above that for new wrought-iron pipe. The average of the values for 1-in. pipe on which data are available gives values about 50 per cent higher than for wrought-iron pipe. For smaller sizes there are not enough data available from which to make any worthwhile estimate of the increase of friction factor, but it is probable that the figure given would be too small for sizes under 1/2 in. in diameter.

The tests by Feely and Riggle[19] on 1/8-in. standard galvanized pipe bought from a supply house are shown in Fig. 5. The curve as run showed a friction factor over 6 times that of a rough pipe when the measured pipe size was used in making the calculations. In order to check the pipe

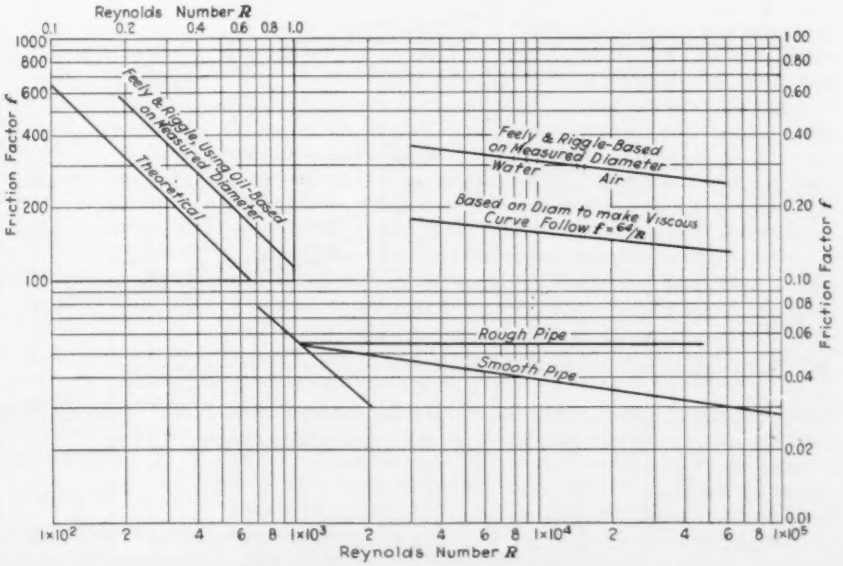

FIG. 5 TESTS BY FEELY AND RIGGLE

[19] Feely and Riggle, "Flow of Fluids in Small Pipes," unpublished thesis, University of Pittsburgh.

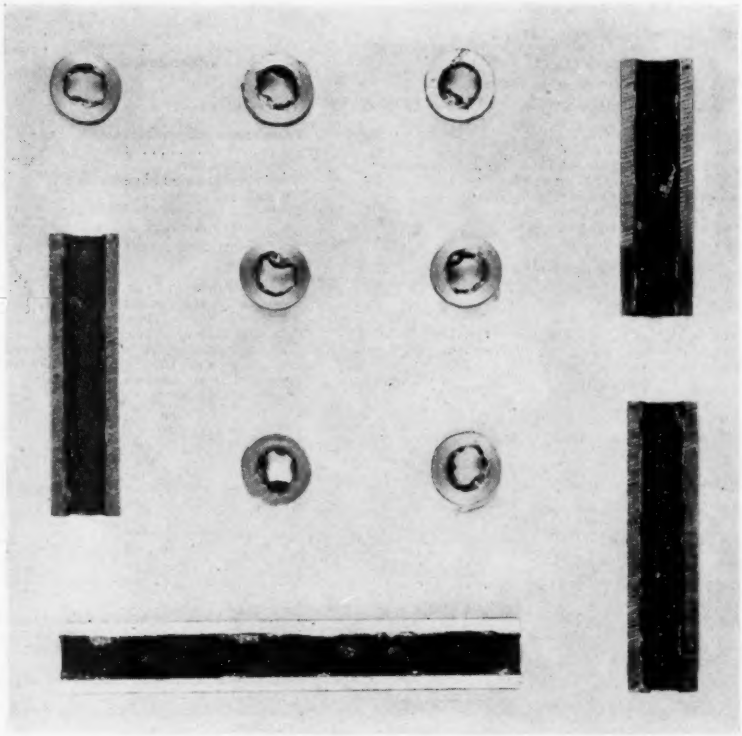

FIG. 6 LONGITUDINAL AND TRANSVERSE SECTIONS OF GALVANIZED PIPE

size a series of tests using a lubricating oil were made at Reynolds' numbers between 0.2 and 1, giving a friction factor between 600 and 100, which does not check with the theoretical curve. A correction of the diameter to make the results coincide with the theoretical curve brings about a reduction of the friction factor to one-half of its value when based on the measured value of the diameter.

This correction still does not show why the friction factor should be so much higher than that for a rough pipe as defined later. In order to find some plausible explanation the author examined the pipe by cutting a large number of sections from it. Some typical sections were machined and are shown in Fig. 6. The projections in the pipe were metallic and resulted from galvanizing. The sections were milled from the pipe, and as a result some of the smaller deposits on the edges were knocked off in machining. The resulting section is therefore not as irregular as the actual pipe, but shows the order of magnitude of the roughness. One of the longitudinal specimens will be seen to show half of the section almost filled with deposits. A pipe with a roughness relatively as large as this has many other factors introduced which affect the flow resistance besides the wall. In a set-up with a change of section it is recognized that there may be quite high losses due to sudden contractions or enlargements, and in this pipe the same type of

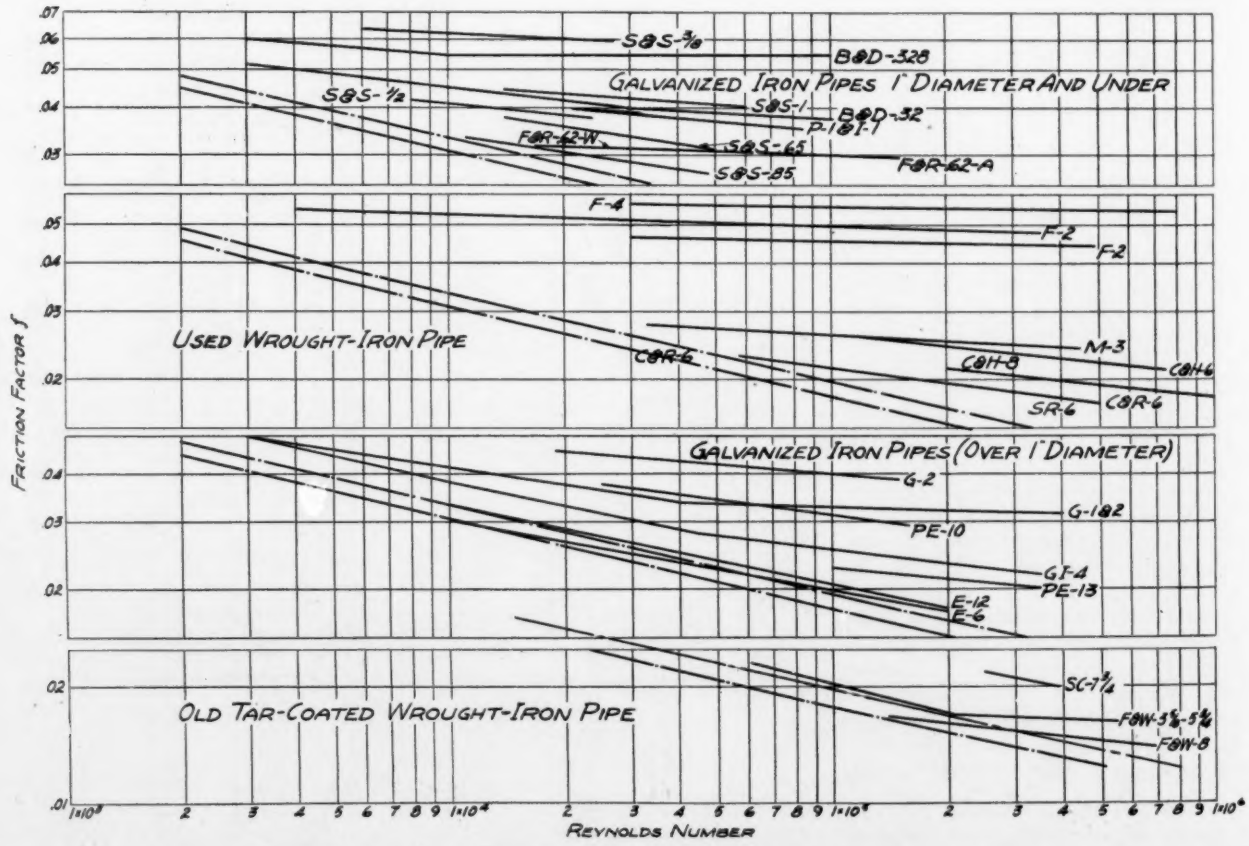

FIG. 7 FLOW IN GALVANIZED, USED, AND OLD TAR-COATED WROUGHT-IRON PIPES

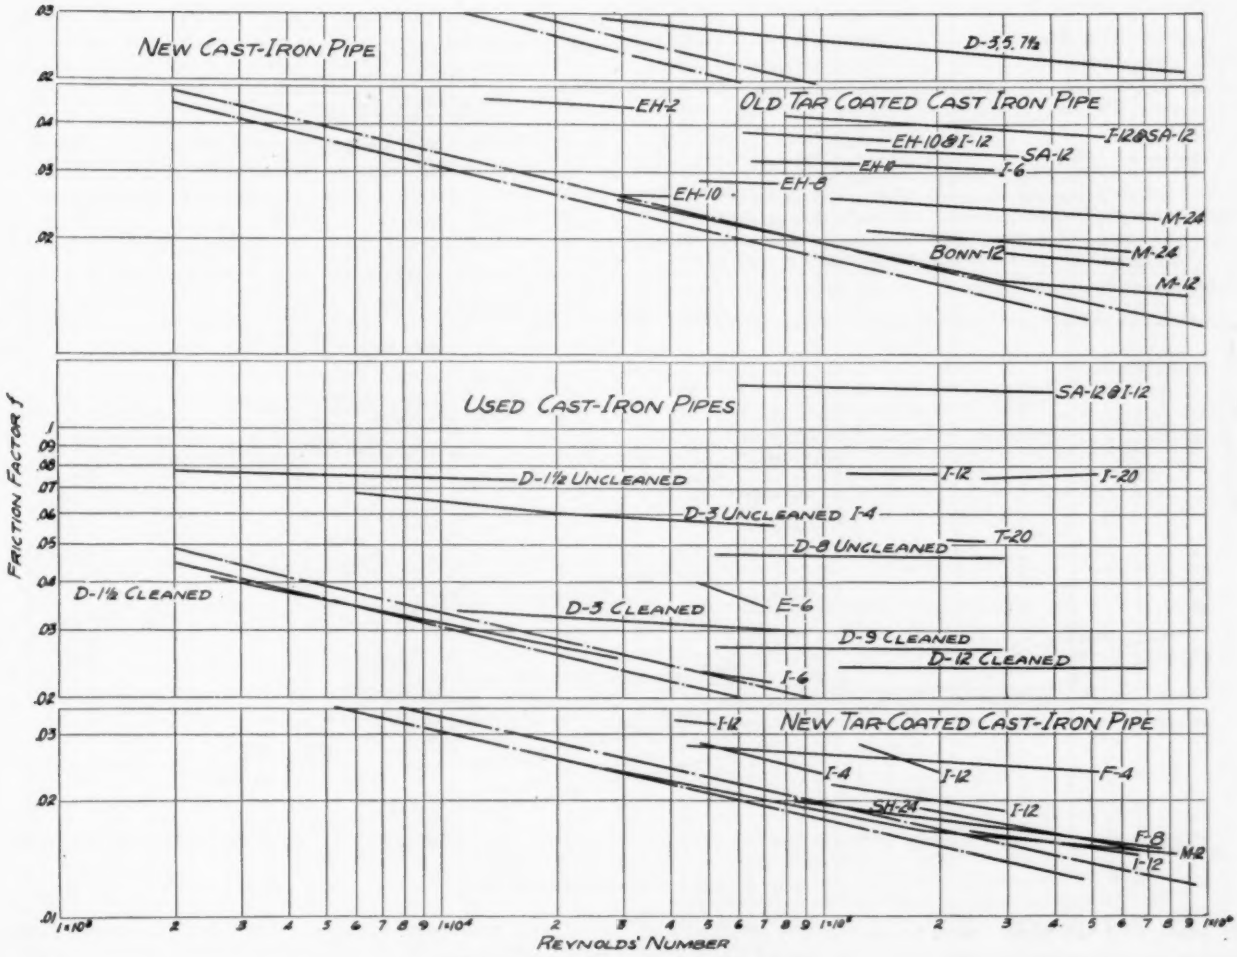

FIG. 8 FLOW IN CAST-IRON PIPES

losses would be present. There would also be additional losses caused by the fact that the roughness projections occur at different positions around the pipe, giving an effect such as occurs at elbows, sharp curves, valves, etc.

This pipe illustrates the condition that can exist in small galvanized pipes and also in small used corroded pipes. For larger sizes the condition will not be so exaggerated.

For the sizes over 1 in. in diameter, the data are meager and inconsistent. The tests by Gibson show the values for 2-in. pipe to be about 50 per cent higher than the average for wrought iron. The tests by Emswiler indicated that for large diameters the effect of galvanizing decreases quite markedly, as would be expected.

About all that can be concluded from the tests on galvanized iron pipe is that the friction factor should be assumed to be at least 50 per cent greater than for ordinary new steel pipe in sizes up to 2 or 3 in. in diameter. In larger sizes the effect is apparently considerably reduced, and for very small sizes is greatly increased. Because of variations from pipe to pipe a large number of tests would have to be made before any reliable values could be decided upon for the range of friction factor for galvanized pipe.

5 USED WROUGHT-IRON PIPE (Fig. 7, Table 3)

As would be expected, the friction factor for used pipe varies a great deal from pipe to pipe. Several very interesting general conclusions can be drawn from the data collected on this kind of pipe, even though these are insufficient to give quantitative results.

The results of the tests by Freeman are very useful in setting up a basis for studying other kinds of very rough pipes. The pipes tested by Freeman are very accurately described[18] and are said to be very rough, but he states that there was no change of diameter and no accumulation of material on the walls of the pipe. He describes these pipes as having some rust scale and pits from $^1/_{64}$ in. to $^1/_{32}$ in. deep. The first thing that will be noticed about his results is that the friction factor is practically independent of the velocity, viscosity, and density. That is, the pressure drop varies as the velocity squared and not as a power between 1 and 2. The second is that if these lines are projected to low values of Reynolds' numbers they will average a point about where the curves for all pipes are started.

From these facts it would be concluded, first, that as the roughness of the pipe increases, the curve for f would approach the horizontal line; second, that if the correct diameter is used, the curve should always pass through the critical point when this pipe becomes very rough.

On this basis we could set up a hypothetical completely rough pipe in which the friction factor was constant in the turbulent region, and the value of the friction factor would be the same as for all pipes at the critical velocity. Here we just limit the roughness to such an order of magnitude as not to introduce contraction effects in the pipe.

The results on the larger pipes show only an average increase of 20 per cent over that for new pipe. The curve by Schoder on a pipe used in a heating main shows values slightly less than for

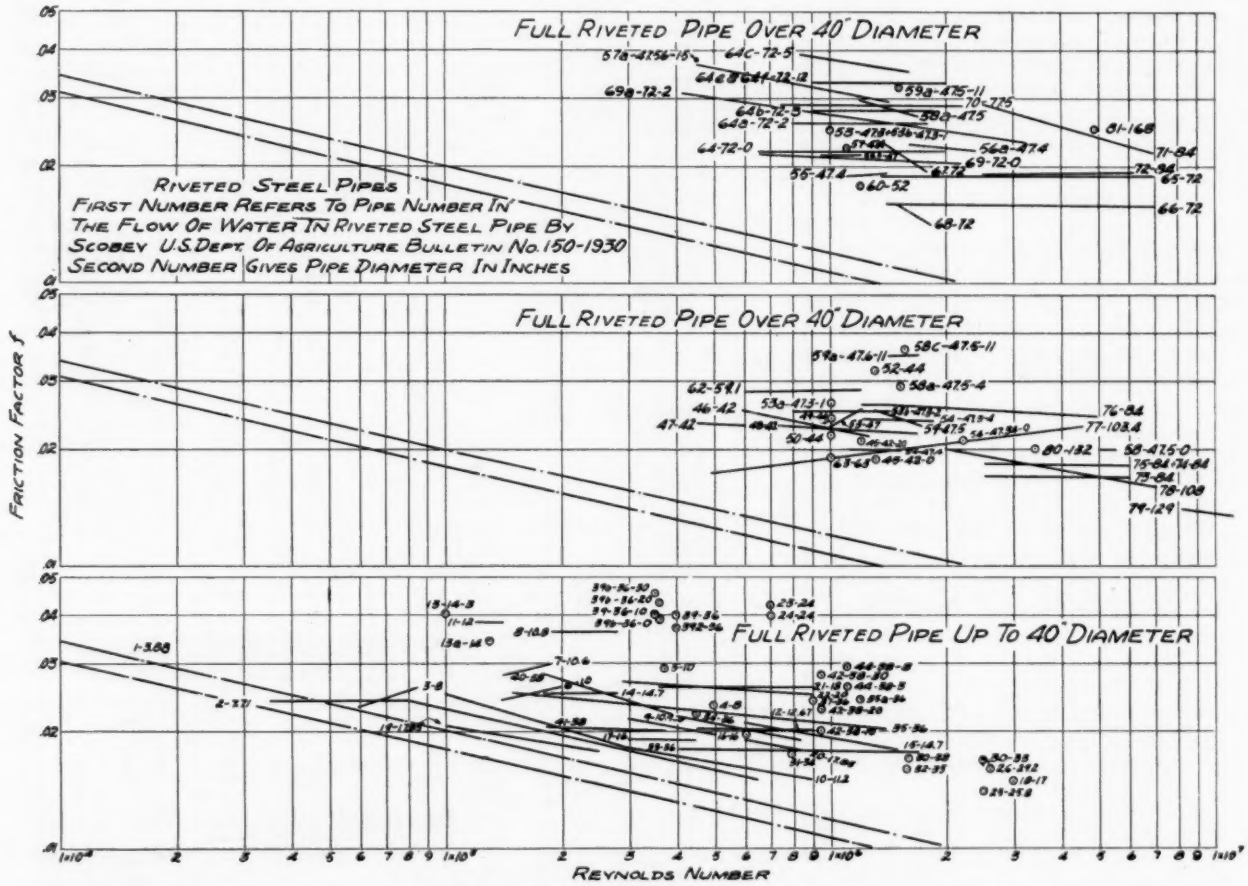

FIG. 9 FLOW IN RIVETED STEEL PIPE

the average for new pipes. Such results could be obtained with pipes with scale present when they were new, and with use, if the scale were removed, f would be reduced. From the tests on large pipes it might be concluded that the effect of use would be inconsiderable unless there was excessive corrosion or accumulation of material in the pipe.

Any accumulation of dirt, sand, organic matter such as paraffin, or other substances in a pipe, will reduce the effective diameter and give an apparent friction factor very much higher than the value on the basis of the hypothetical completely rough pipe discussed above. Also with the accumulation of material, there will probably be variations in diameter which will cause additional energy losses because the fluid will be alternately accelerated and decelerated. This will have little effect except in very small pipes.

6 OLD TAR-COATED WROUGHT-IRON PIPES (Fig. 7, Table 3)

There are very few data on which to base any very general conclusions, but those available indicate values of f much lower than for old uncoated wrought-iron pipes. This is probably due to the fact that the coating checks corrosion or deposition of calcareous material.

7 NEW CAST-IRON PIPE (Fig. 8, Table 3)

The results of these tests differ greatly from what would ordinarily be expected. However, Darcy's notes state that the pipe had a remarkable degree of polish. The values correspond closely for those of new $^3/_4$-in. steel pipe. The data are very meager, but indicate that with well-polished cast-iron pipe the friction losses would not be over 25 to 50 per cent greater than for new steel pipe of the same diameter. The rougher pipes would show values corresponding more nearly with those for the perfectly rough pipe. There seemed to be many values recommended for new cast-iron pipe, but apparently Darcy's experiments were the only ones on which the experimental data could be found.

8 USED CAST-IRON PIPE (Fig. 8, Table 3)

This set of experiments shows the effects of thin deposits on the inside of pipes. The tests by Darcy on cleaned and uncleaned pipes show the large change of friction factor with changes in surface and diameter. The curves for these very rough pipes are quite flat, indicating that the variation with viscosity and velocity is small. The tests by Safford and Iken are interesting because they are on very old pipes and show that there was some change in effective diameter. It is seen that the cleaned pipes give a friction factor such that if the curve were projected to low values of Reynolds' numbers, the point would not lie above the critical point. These data corroborate the theory already given.

9 NEW TAR-COATED CAST-IRON PIPES (Fig. 8, Table 3)

These tests show values that are about 25 per cent higher than those for wrought-iron pipes of the same size (4 in.). For larger sizes, the values seem to average somewhat lower than the values for 6-in. steel pipe.

10 OLD TAR-COATED CAST-IRON PIPES (Fig. 8, Table 3)

These tests show a wide variation in friction factor and a much higher value therefore than for new tar-coated pipes. The effect of tar coating is probably to reduce corrosion and the accumulation of calcareous materials. This is shown by the fact

that the curves in general do not go much above a horizontal line through the critical point. Several of these are curves for pipes in which there was a slight incrustation.

11 Riveted Steel Pipe (Fig. 9)

The data used in Fig. 9 were taken from U. S. Bureau of Agriculture Bulletin No. 150 (1930), by Fred Scobey. The curves show the results of field tests on pipe lines used for irrigation and power purposes. No discussion of the various pipes will be attempted, and those desiring information concerning them are referred to the original source. Mr. Scobey states that sheet-metal pipes with flat rivets as used for irrigation or low-pressure installations have a capacity appreciably above that of plate-type pipes used in high-pressure installations. The greater capacity means

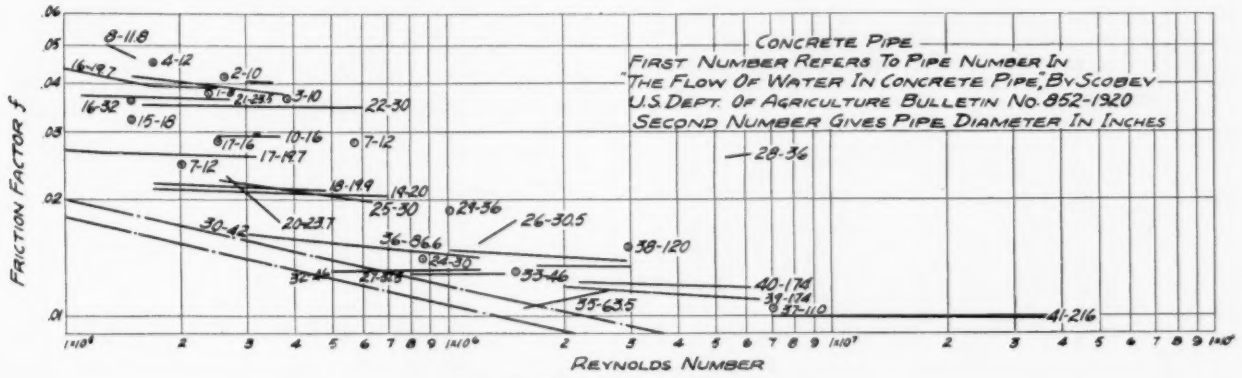

Fig. 10 Flow in Concrete Pipe

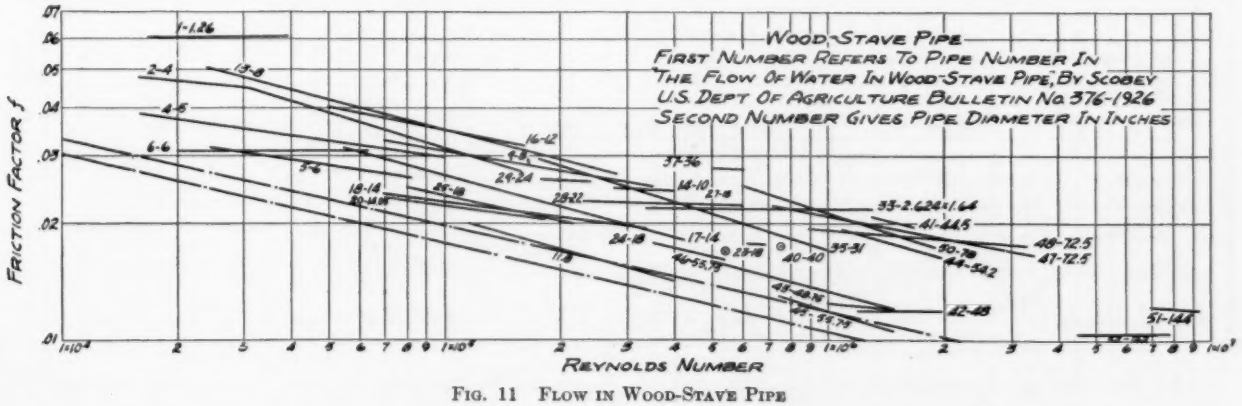

Fig. 11 Flow in Wood-Stave Pipe

that these pipes have a lower friction factor. This conclusion agrees with that arrived at by Mr. Pigott[20] from a consideration of roughness of pipes, in which he pointed out that the roughness of a light sheet-steel duct or pipe for low pressures such as flues or low-pressure irrigation work would be much less than for heavy pipe used for penstocks and high-pressure installations.

Another important point is that the friction factor for this type of pipe does not exceed 0.045, even for pipes in use as long as 30 years or more. Considering the relative roughness of this type of pipe, it is seen to support the previous theory that unless there is a change in diameter the friction factor will not exceed the value at the critical velocity.

12 Concrete Pipes (Fig. 10)

The data for these curves have been taken from U. S. Department of Agriculture Bulletin No. 852 (1920). They are of interest because they represent a type of pipe usually considered rough and because they include values at particularly high Reynolds' numbers. Again the data on small sizes show values below the value at the critical number. The lines are predominantly horizontal. It will be noticed that with one exception the values at high Reynolds' numbers are relatively low, this one exception being on a relatively small pipe. Several of the curves have slopes that are questionable, but this is probably because the range of velocities is not sufficient to permit an accurate curve to be drawn. Here again the data were plotted and a curve that was considered to be nearer an average was selected. In general the experimental points showed quite a spread, and in all cases an attempt was made to select a mean curve.

13 Wood-Stave Pipe (Fig. 11)

These data were taken from U. S. Department of Agriculture Bulletin No. 376 (1927). The curves again fall within the limit set for rough pipes except for the 1.26-in. size, which is not far out. Hopf[21] has concluded from his summary that the curves for wood-stave pipe would be parallel to the brass line. The data given here, however, show almost an equal tendency for the lines to be horizontal at the higher Reynolds' numbers.

14 Artificially Roughened Pipe

A great deal of work has been done by German investigators on artificially roughened pipe. Fromm,[22] Fritsch,[23] Schiller,[24]

[20] Pigott, "The Flow of Fluids in Closed Conduits." Paper before National Process Meeting, Buffalo, June, 1932.

[21] Hopf, "Handbuch der Physik," vol. 7, p. 149.

[22] Fromm, "Flow in Rough Pipes," *Zeit. für Angew. Math. u. Mech.*, vol. 3 (1923), pp. 339–358.

[23] Fritsch, "Turbulent Flow in Pipes," *Zeit. für Angew. Math. u. Mech.*, vol. 8 (1928), pp. 199–216.

[24] Schiller, "Flow in Rough Pipes," *Zeit. für Angew. Math. u. Mech.*, vol. 3 (1923), pp. 2–13.

and Nikuradse[25] have made rather extended studies of the problem, and a very brief outline of their researches will be given here.

Fromm's results are shown in Figs. 12 and 13. He experimented with four degrees of roughness. In his work he used a rectangular section having smooth sides and a rough top and bottom. This set-up permitted an investigation of the effect of depth of section on behavior under a given roughness. The first set of tests were made using a wire net surface having a thickness of 0.115 mm. The curves seem to behave rather peculiarly at low Reynolds' numbers, but at values much above the critical become nearly parallel and horizontal, and a variation with the depth is found for the shallow sections. Even the shallow section shows a value of f not much above that for the ideal rough pipe. A correction of diameter for the surface thickness would bring this value to the line for rough pipe.

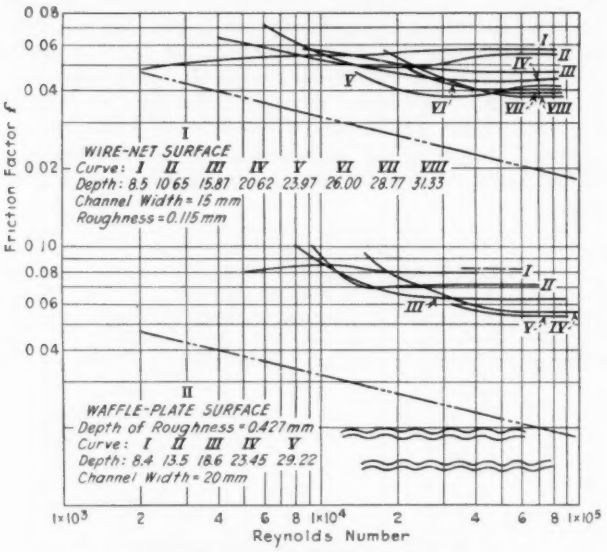

Fig. 12 Flow in Artificially Roughened Pipe

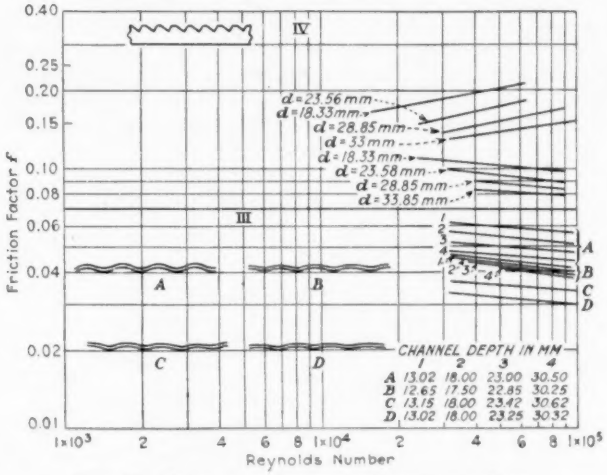

Fig. 13 Flow in Artificially Roughened Pipe

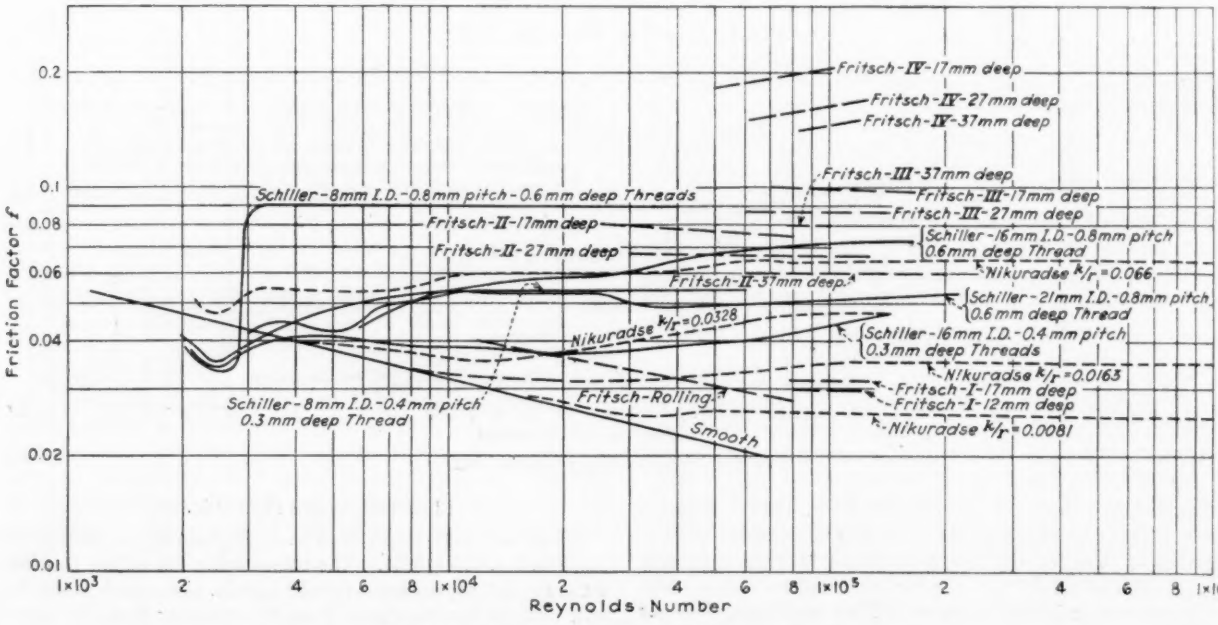

Fig. 14 Flow in Artificially Roughened Pipe

The second series of tests using a waffle-like indented zinc-plate surface have a roughness of 0.427 mm, which means that the difference between the minimum and maximum depth is 10 per cent of the effective depth in the case of the narrow channel. Since it is not certain how this depth was obtained, it cannot be known whether the effective depth is an average or not. If it is an average value, the high friction factor can be explained by using the minimum depth, which would be (8.4 — 0.427) mm. This would reduce the value of f from 0.083 to about 0.058. Since the projections amount to 10 per cent of the depth, contraction and expansion losses might account for the entire loss in case the value given for the depth was the minimum depth.

The sections with a deep channel show an f about equal to the value for a rough pipe. This series of tests also behave in an unusual manner near the critical region.

The third series of tests were made on another corrugated-plate surface which was successively rolled down. The deeper corruga-

[25] Nikuradse, "Flow in Rough Pipes," *Zeit. für Angew. Math. u. Mech.*, vol. 11 (1931), pp. 409–411.

tions show a variation with channel depth, but the smoothed section shows no variation with channel depth. In all cases the values are seen to be below the rough-pipe value.

The fourth series of tests were made using a sawtooth grooved plate with roughnesses 1.5 mm deep. As would be expected, the results show very high friction factors and also a decided variation depending upon the direction in which the flow took place. When flow was against the grooves, the pressure drop varied to a power greater than two, so that some other factor besides wall effect must enter. With roughnesses of this order of magnitude effects such as occurred in the previously described galvanized pipe take place and the results are no longer comparable with those for an ordinary rough pipe.

The results of the tests by Fritsch, Nikuradse, and Schiller are roughnesses of an order of magnitude ordinarily found in corroded pipe, the friction factor would not exceed the value set up for the ideal rough pipe.

15 Miscellaneous (Fig. 15)

The results on spiral riveted pipe show friction factors much higher than on new wrought-iron pipe. This would be expected from the nature of the surface of the pipe. The friction factor is higher for some cases where the flow is against the seam.

The data on natural-gas lines are interesting because they represent actual field tests. The data by Guman have been taken from the *Gas Service Journal*, May, 1930. The numbers on the other points correspond to the test numbers given in the Bureau of Mines' publication.

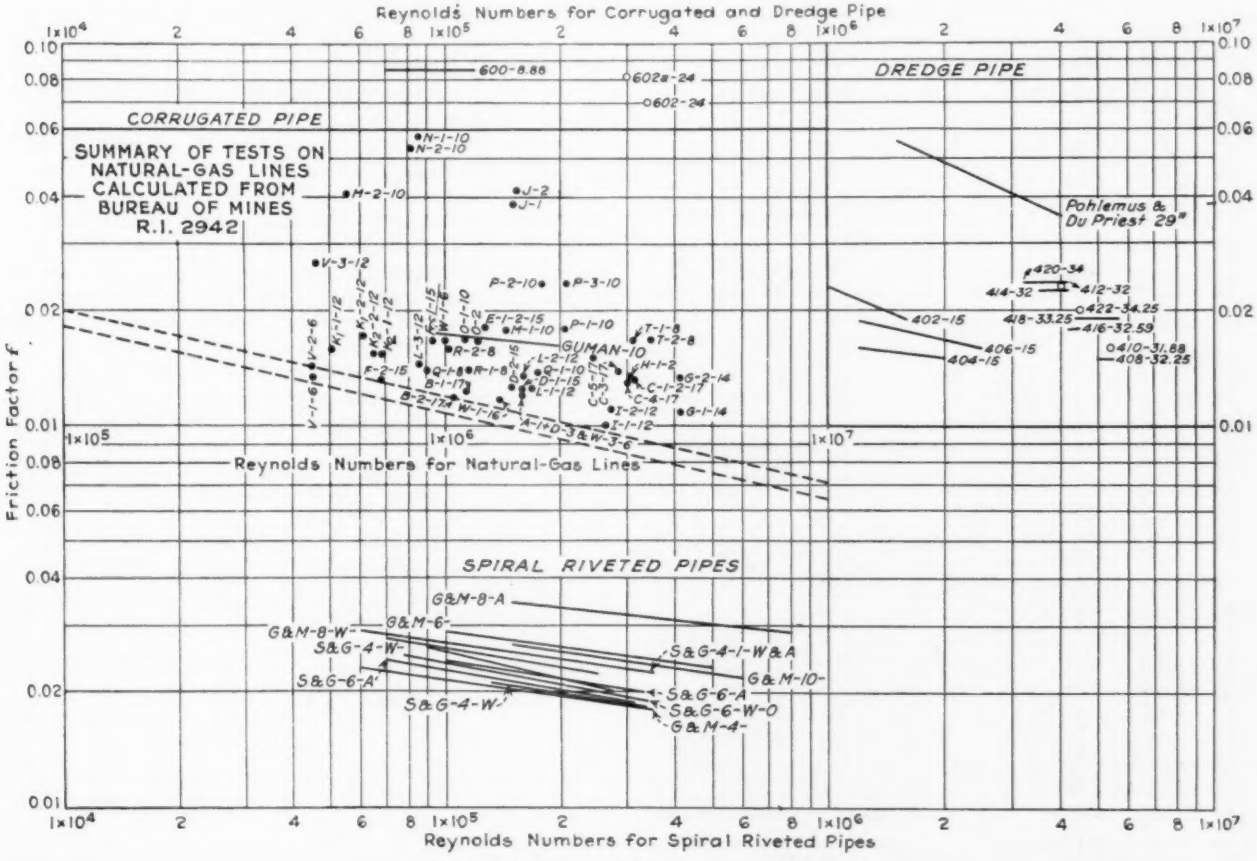

Fig. 15 Flow in Miscellaneous Pipes

shown in Fig. 14. Here again the method of determining the depth or diameter is not definitely known, so no attempt will be made to correct the data. The results obtained by Fritsch are very similar to those by Fromm. The curves marked I are for a roughness that might be found in moderately rough pipes.

The curves for II are similar to that for very rough pipes. Curves marked III and IV are similar to the sawtooth curves of Fromm. Nikuradse's results do not give values above those for rough pipe except for the very roughest pipe, in which case it seems that the original diameter of the pipe was used instead of the working diameter. The use of glue and sand on the inside of the pipes makes the diameter actually smaller than that of the original pipe. A correction for this would bring the friction factor back to the rough-pipe range. In his tests the values of k/r refer to the ratio of the size of sand particles to the pipe radius.

The results on artificially roughened pipes show that with

Since no data are available on the diameters used in the tests on corrugated pipe, little can be said about them.

The data on dredge pipe are seen to give results comparable with those for ordinary pipe, even though there are usually a large number of bends, joints, etc. present in the line.

VII—COMPARISON WITH FORMULAS THAT HAVE BEEN USED

A comparison of the various formulas used in the calculations for fluid flow would be a long study in itself. In order to get a general idea as to the number of and variations in the formulas used the various recommendations made by those who proposed to make f a constant are given. Most of these were taken from the data compiled by Eason[25] and are given in Table 4. It will be seen from an examination of the data that the values vary

[25] Eason, "Flow and Measurement of Air and Gases."

widely. Any constant value of f would apply for a limited range of Reynolds' numbers, but at a low enough value of R it would be seen to give a value less than that for smooth pipes.

VIII—FLOW OF COMPRESSIBLE FLUIDS

1 Flow in Horizontal Pipes

The general energy equation ordinarily used for the flow of compressible fluids in horizontal pipes has the form

$$\frac{dp}{\rho} + \frac{vdv}{g} + \frac{fv^2dx}{2\,gD} = 0$$

where ρ = density, p = pressure, v = velocity, V = volume, W = weight of fluid per second, and A = area of pipe. This equation can be derived by using Bernoulli's theorem or from the energy relation as given by Goodenough.[27] This equation is not difficult to solve for isothermal flow, but is very cumbersome to use. Generally the term vdv/g, which is the one taking into account the change of kinetic energy, is omitted because it is very small in most problems.

When f is expressed as a function of the Reynolds number, the equation is justified in its simpler form. In finding the value of f from any set of experiments it will be remembered that the experimental values were substituted in the equation $\Delta h = flv^2/2gD$ and the equation was solved for f. This value of f was then plotted against the corresponding value of R. In the discussion of the flow in smooth pipes it was pointed out that the experimental results gave the same friction factor for both compressible and incompressible fluids. Also in the case for several sizes of rough pipe this same result was noted. The equation for flow of compressible fluids will be derived on the basis of the experimental data, which show that practically the drop in pressure head is given by

$$dh = \frac{fv^2dx}{2gD} \text{ for a length } dx.$$

$$dp = dh\,\rho = \rho\frac{fv^2dx}{2gD} \quad [1]$$

For isothermal flow we have from Boyle's law

$$p_1V_1 = pV = p_2V_2 \quad [2]$$

The equation of continuity gives

$$Av = V \quad [3]$$

$$v = \frac{p_1V_1}{pA} \quad [4]$$

$$\rho = \frac{W}{V} = \frac{W}{Av} \quad [5]$$

$$f = \phi\left(\frac{Dv\rho}{\mu}\right) = \phi\left(\frac{Dv}{\mu}\frac{W}{Av}\right) = \phi\left(\frac{DW}{A\mu}\right) \quad [6]$$

Equation [6] shows that the friction factor depends on the size of pipe, viscosity of fluid, and the weight of fluid flowing. Then for any given set of conditions, f is constant. The friction factor depends only on the initial or final conditions of the gas and can be considered constant in Equation [1].

$$v = \frac{W}{A\rho} \quad [7]$$

so that Equation [1] becomes

$$dp = \frac{fWv\,dx}{2AgD} \quad [8]$$

[27] Goodenough, "Principles of Thermodynamics," Henry Holt & Co.

Substituting for v in terms of p,

$$dp = \frac{fWp_1V_1dx}{2AgDpA}$$

$$pdp = \frac{fWp_1V_1}{2gDA^2}dx, \text{ or } \int_{p_2}^{p_1} pdp = \int_0^l \frac{fWp_1V_1dx}{2gDA^2}$$

$$p_1^2 - p_2^2 = \frac{fWp_1V_1l}{gDA^2} \quad \ldots\ldots\ldots\ldots\ldots [9]$$

$$p_1V_1 = p_1v_1A = p_2v_2A \quad \ldots\ldots\ldots\ldots\ldots [10]$$

$$p_1^2 - p_2^2 = \frac{fWp_2v_2l}{gDA} = \frac{f\rho Av_2^2p_2l}{gDA}$$

$$p_1 = \sqrt{p_2^2 + \frac{fWp_2v_2l}{gDA}}$$

$$p_2 = \sqrt{p_1^2 - \frac{fWp_1v_1l}{gDA}}$$

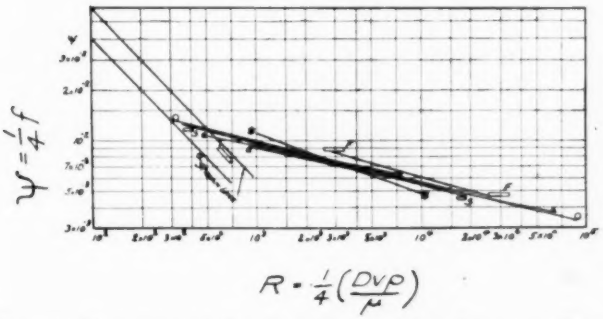

FIG. 16 VARIATION IN FRICTION FACTOR WITH SHAPE OF PIPE SECTION

2 FLOW IN VERTICAL PIPES

(*a*) *Flow Up the Pipe.* In this case there is in addition a loss in head due to the vertical displacement and the equation becomes

$$dh = \frac{fv^2dx}{2gD} + dx$$

$$dp = \rho dh = \frac{f\rho v^2dx}{2gD} + \rho dx$$

$$= \left[\frac{f\rho v^2}{2gD} + \rho\right]dx$$

$$= \left[\frac{fWv}{2AgD} + \frac{W}{Av}\right]dx = \left[\frac{fWp_1V_1}{2A^2gDp} + \frac{Wp}{p_1V_1}\right]dx$$

Let

$$\frac{fWp_1V_1}{2A^2gD} = C_1 \text{ and } \frac{W}{p_1V_1} = C_2$$

then

$$dp = \left[\frac{C_1}{p} + C_2p\right]dx = \left[\frac{C_1 + C_2p^2}{p}\right]dx$$

$$\int_{p_2}^{p_1} \frac{pdp}{C_1 + C_2p^2} = \int_0^l dx$$

$$\frac{l}{2C_2}\log\frac{\left(p_1^2 + \frac{C_1}{C_2}\right)}{\left(p_2^2 + \frac{C_1}{C_2}\right)} = l$$

or

$$\frac{\left(p_1^2 + \frac{C_1}{C_2}\right)}{\left(p_2^2 + \frac{C_1}{C_2}\right)} = e^{2C_2l}$$

(*b*) *Flow Down the Pipe.* In this type of flow the loss of head is decreased, for at every point the weight of fluid above the point increases the pressure. The equation would then be

$$dp = \frac{f\rho v^2dx}{2gD} - \rho dx$$

This change means that the sign of C_2 in the preceding equations would be changed; otherwise there is no difference. We can then write the solution directly as

$$\frac{\left(p_1^2 - \frac{C_1}{C_2}\right)}{\left(p_2^2 - \frac{C_1}{C_2}\right)} = e^{-2C_2l}$$

IX—THE MEAN HYDRAULIC RADIUS AS A CRITERION FOR FLOW

The equations and curves for making flow calculations have been given for circular pipes. Often it is necessary to make calculations for non-circular shapes, annular shapes, and cases with a free surface. In order to handle these problems a term called the mean hydraulic radius has been devised. This has been selected on the supposition that the resistance for pipes of the same area is proportional to the fluid in contact with the surface of the pipe. If we represent this mean hydraulic radius, or profile radius as it is sometimes called, by r, we have

$$r = \frac{\text{area}}{\text{wetted perimeter}}$$

Schiller[28] has done a large amount of experimental work on this subject. His results are shown in Fig. 16, which is taken from the "Handbuch der Physik." It is seen that for ordinary shapes the values of the friction factor in the turbulent region are very close to those for a circular shape. In the streamline or viscous region the variation is as much as 50 per cent more than for circular shapes. Caldwell has made experiments with different shapes in this region and found the discrepancy to be large in some cases. The case of streamline flow can be expressed by the differential equation[29]

$$\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} = \frac{\Delta p}{\mu}$$

for flow in a uniform section; x and y represent the coordinates of the section, Δp the drop in pressure per unit length, and μ the viscosity of the fluid.

The mathematical solution of this equation is possible in only a few special cases, which are the sections for which the torsion problem has been solved. The soap-film analogy proposed by Prandtl, and which is used in solving complicated torsion problems, can be applied to this problem. The differential equation of the soap film is given by[30]

$$\frac{\partial^2 z}{\partial x^2} + \frac{\partial^2 z}{\partial y^2} = \frac{\Delta p}{2T}$$

[28] Hopf, "Handbuch der Physik," vol. 7, p. 143.
[29] Lamb, "Hydrodynamics," Cambridge University Press.
[30] "Mechanical Properties of Fluids," D. Van Nostrand Co., p. 230.

where z is the height of the soap film above the section, x and y the coordinates of the section, T the tension in the film, and Δp the pressure difference on the two sides of the film. If then we let

$$\frac{\Delta p}{\mu} = \frac{\Delta p}{2T}$$

the velocity at any point in the section will correspond to the ordinate of the soap film and the volume of the soap bubble will correspond to the volume of flow. Methods for measuring these quantities have been devised for use in solving the torsion problem. The method described also permits a mental picture of the approximate velocity distribution over such a section if quantitative results are not desired. Such types of sections as thin annular spaces correspond to a long rectangular section, etc. By use of the values determined for the torsion of rectangular sections it is possible to calculate flow in annular spaces.

For streamline flow it is only safe to base the flow on the mean hydraulic radius if the section is circular or very nearly so. The following solution for the flow in a concentric annular section is given in Lamb's "Hydrodynamics."[31] If r is the large radius of the annulus and a the smaller radius, the quantity discharged is given by

$$Q = \frac{\pi}{8\mu}\frac{\Delta p}{l}\left[r^4 - a^4 - \frac{(r^2 - a^2)^2}{\log r/a}\right]$$

For a circular pipe

$$Q = \frac{\pi r^4}{8\mu}\frac{\Delta p}{l}$$

where Δp represents the drop in pressure.

If we take $a = 0.1\ r$ the mean hydraulic radius will be practically the same for both cases but the flow for the annular space will be

$$Q = \frac{\pi}{8\mu}\frac{\Delta p}{l} r^4 \left[1 - \frac{1}{\log_e 10}\right] \text{approximately}$$

$$= \frac{\pi}{8\mu} \times \frac{\Delta p}{l} r^4 \left(1 - \frac{1}{2.3}\right) = 0.53\,\frac{\pi r^4}{8\mu}\frac{\Delta p}{l}$$

For a circular pipe

$$Q = \frac{\pi r^4}{8\mu} \times \frac{\Delta p}{l}$$

So for the same pressure drop the flow in the annular space in which the inner radius is one-tenth of the outer radius is only 53 per cent of that for a circular pipe of the same outside diameter.

A bibliography of this subject is given by Bateman[14] in his recent book, together with a brief discussion of the principal works on the subject.

CONCLUSIONS

Some of the more important conclusions to be drawn from the foregoing data are:

1 The friction factor is independent of the fluid flowing for the same values of R.

2 The friction factor for drawn brass pipe varies only ±5 per cent from an average value and is substantially independent of the pipe size and fluid flowing for the same value of R within the range encountered in practice.

3 The friction factor for new steel pipe varies with the size and varies about ±10 per cent from an average value. The reason for the variation with size is because the roughness increases with decrease in diameter.

4 The data on used and artificially roughened pipes show that if the roughness is not large enough to cause contraction and enlargement losses, the friction factor never exceeds the value 0.054.

5 The mean hydraulic radius can be safely used as a criterion only in the turbulent region.

6 Special care should be taken in the selection or determination of the diameter.

Of these conclusions, the most important one is that there is an upper limit for the friction factor. While this upper limit has not been proved conclusively, the data show that unless the roughness becomes of such an order of magnitude as to cause effects such as occur when there are contractions and enlargements, the friction factor will not become greater than 0.054. The limits of roughness are yet to be determined and will probably have to be ascertained by taking velocity traverses along as well as across the pipe.

The upper and lower limits of the friction factor having been determined, the next problem is the selection of values for various types and sizes of pipes. This problem has been discussed by R. J. S. Pigott in a recent paper.[20] His curves for the various types and sizes of pipe are the best and most extensive that have been proposed for design work and should be considered in connection with the present paper.

The effect of diameter on flow is worthy of further mention. It has been seen that $v = V/A = 4V/\pi d^2$, so that

$$\Delta h = \frac{8flV^2}{g\pi^2 D^5} \text{ or } f = \frac{\Delta h g \pi^2 D^5}{8lV^2}$$

From this it can be seen that a small change in D would produce a very large change in f. Since all quantities in the equation for Δh are fixed except D, the value of f will vary inversely as D^5. If, for example, in the design of a pipe line the value of f is selected and a value of $D = 1$ is used while the actual value of $D = 0.9$, the calculated Δh would be $8fV^2/g\pi^2$, whereas the actual Δh would be $1.7 \times 8fV^2/g\pi^2$. The pressure drop would actually be 70 per cent greater than the value based on $D = 1$. Experimental results would show f 70 per cent higher than was actually the case. For design purposes where incrustations are expected it is much safer to estimate the ultimate diameter and use $f = 0.054$ than to estimate the ultimate value of f.

In the present study an attempt was made to obtain all the data available on flow in pipes under pressure, but in a number of cases references were not available and some data have no doubt been overlooked. Many engineers have experimental data which have not been published and which would be a valuable addition to this study. Because of the expense of publishing the individual curves with comments, and the need for economizing at this time, the author would be glad to receive and compile them in an appendix, together with a table giving the name of the experimenter, the fluid used, and brief comments.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Mr. R. J. S. Pigott, who proposed this research problem, and whose personal interest and help have made this paper possible. To him credit is due for seeing the practical possibilities of the work. The author also acknowledges the assistance of Mr. H. G. Botset, who has made many of the German translations, and his indebtedness to Prof. Linn Helander and Dr. Morris Muskat for their many helpful suggestions.

[31] Lamb, "Hydrodynamics," p. 555.

Discussion

J. M. Spitzglass.[32] The author's analysis shows three grades of fluid conduits: the smooth pipe, the rough pipe, and the irregular pipe. The smooth pipe having little disturbance to cause and to accelerate the condition of turbulence retains the condition of streamline flow to a larger value of the Reynolds number and a correspondingly lower value of the friction coefficient. The flow in the rough pipe "bursts" into the turbulence much sooner, and the "ideal" rough pipe, as the author has shown, makes an abrupt change from one mode of motion to the other. In other words, the change is so complete that from this point on the friction drop of pressures becomes proportional to the square of the velocity, and therefore the coefficient f remains constant. In the smooth pipe, however, not only does turbulence start at a lower value of f, but the turbulence when started is not as yet complete. The value of f, as shown, continues to drop, indicating that the complete proportionality of V^2 is approached only when the Reynolds number becomes very large.

Let us assume a given flow in a pipe of intermediate roughness where the friction drop is just reaching the point of porportionality to V^2. If from this point on the friction coefficient retains the same value, it would indicate that complete turbulence has been reached for the given condition. On the other hand, since the value of f at that point is necessarily less than the value of f in the "ideal" rough pipe, we must admit that the accidental turbulence in the smoother pipe is less effective than the corresponding turbulence in the rough pipe. This being the case, it is just as natural to assume that a further increase in the turbulence factor may increase the effectiveness of the turbulence, with the result that from this point on the friction coefficient should increase instead of decreasing with the increase of the turbulence factor.

Tests made some 20 years ago for the Peoples Gas Light & Coke Company of Chicago on the flow of illuminating gas in service pipes, the results of which were published by the Illinois Gas Association in 1912, have led to the belief that in the case of commercial gas pipes the coefficient of friction reaches a minimum value of 0.00367 in the 10-in. and 12-in. pipes. From this minimum the coefficient increases considerably as the size of the pipe decreases, and it also increases somewhat as the size of the pipe increases.

Of course, tests on commercial pipes, usually of unknown irregularity, are not conclusive to establish an assumed law of variation in the physical quantity. The unfortunate part of it is that with few exceptions the data on smaller sizes come from laboratory experiments, while the data on larger sizes come from tests on commerical pipe lines. The writer would like to ask the author whether his extensive analysis of the existing data would indicate a proof or a disproof of the assumption that under certain conditions the friction coefficient of smooth pipes may increase instead of decreasing with the increase of the turbulence resulting from the increase of the diameter of the pipe.

Theodore Baumeister, Jr.[33] The Reynolds number criterion has been accepted for some time as the most exact basis of comparing fluid dynamic circumstances. No one, however, until the present author, has attempted to analyze the bulk of older empiric and semi-empiric methods and to reduce these data to the common base of Reynolds' numbers.

The weakness of the Reynolds number method for the estimation of frictional resistance, aside from its cumbersome arithmetic and manipulation, rests in the designer's inability accurately to predict the relative friction coefficients when pipe other than some convenient laboratory standard is to be used. The author has contributed much to alleviate this condition by a careful reconsideration of available fact data. The statement at the close recites briefly the next problem of correlation for design purposes. It would be further contributive if the author would list the relative values of friction factor for the outstanding classes of commercial piping and duct work. Gibson gives such values, and the writer has used the following with some degree of success in the design of piping systems:

New, clean smooth, seamless drawn brass tubing	1.0
New galvanized-iron pipe	1.2
High-pressure steam lines	1.3
Sheet-metal ducts	1.3
New black wrought-iron pipe	1.4
New cast-iron pipe	1.5
Very smooth concrete pipe	1.8
Fiber ducts	5.0

In the light of the author's research these and similar tabulations must be open to criticism, and the author's comments on them should prove pertinent.

R. P. Genereaux.[34] Schiller is quoted as concluding 1160 to be the critical Reynolds number. As Schiller's Reynolds' number is $ru\rho/\mu$, where r is radius, the value 1160 should be multiplied by 2 to obtain $du\rho/\mu$, or 2320. The author states that "there are no experimental data on flow at very high Reynolds' numbers for smooth pipe." Since Mr. Kemler's correlation was made, Nikuradse has published his most recent data on the flow of water in smooth pipes (see *Forschung*, 3; Forschungsheft, 356, 1–36, 1932, Sept.–Oct.). With inside diameters of 10, 20, 30, 50, and 100 mm, Nikuradse obtained pressure-drop data for a range of Reynolds' number (in consistent units) from 3×10^3 to 3240×10^3, which upper value is somewhat higher than any for this case heretofore published. He compares his data with those of Stanton and Pannell and of Schiller and Hermann, and recommends a curve beyond the Reynolds numbers of these investigators. At a Reynolds number of 10^7, Lees' formula for Stanton and Pannell's data gives $f = 0.00937$, Schiller gives $f = 0.00854$, and Nikuradse gives $f = 0.00805$ by his formula $f = 0.0032 + (0.221/Re^{0.237})$.

Glen N. Cox.[35] It is regretted that the author did not present data on the behavior when streamline flow existed. To say that this type of flow can be handled mathematically is one thing, but to know that one can rely upon the mathematical analysis is quite another. For very viscous fluids, it may be quite difficult to obtain velocities great enough to produce turbulent flow.

The writer has had occasion to make some tests on the resistance of molasses in pipe. In this work, molasses that was not quite as thick as the black strap ordinarily encountered was pumped through a $1^1/_2$-in. pipe having a gage length of 42.16 ft. The pressures were measured with Bourdon gages and the discharge was weighed. The results of these tests did not approach the critical Reynolds number. With a temperature of 20 C, it would require a velocity of 65 ft per sec in the $1^1/_2$-in. pipe to obtain 2000 for Reynolds' number. This velocity would be accompanied by a pressure drop of 810 lb per sq in. for each 100 ft length of pipe.

This example clearly shows the impossibility of operating in the turbulent zone without heating the molasses considerably. There are also other very viscous fluids that must be pumped and which would also follow streamline flow. For this reason, the writer believes that some consideration should have been given data covering this type of flow.

LYMAN M. VAN DER PYL.[36] The paper is valuable for those interested in the flow of fluids as it puts all previous work before an investigator. There are a few recent papers that were not included, and abstracts of them are given herewith.

Naumann's "Experimentelle Untersuchungen über die Entstehung der Turbulenten Rohrströmung," in *Forschung auf dem Gebiete des Ingenieurwesens*, 2, 85–98 (1931), deals with the method by which turbulent flow starts. Photographs show the turbulence in various forms as the Reynolds number increases.

In Wunsch and Zipperer's "Versuche zur Bestimmung des Fortleitungswiderstandes der Ferngasleitung Hamm-Hannover," *Gas- und Wasserfach*, 57, 428–33, 672 (1932), the line used was a new gas line 500 mm i.d., 95.927 km long. The inner surface of the pipe had a thin coating of bitumen. The test was made with air, with the following results:

Reynolds' number	Friction factor
146800	0.0168
147000	0.0168
247500	0.0152
244400	0.0159

The data fit very well on the curve of Stanton and Pennell, which was checked by Jakob and Erk. A shorter account of the same test is given by Zipperer in the *Z.V.D.I.*, 76, 916–917 (1932).

A third paper is Viesohn's "Untersuchen über Druckhöhenverluste in Rohrleitungen und Armaturen für die Hausleitungen der Wasserversorgung," *Gas- und Wasserfach*, 75, 679–685 (1932). His work was done in pipes 40 m long and 10 to 50 mm in diameter. The materials were lead, brass, copper, and galvanized iron, all new. The results are expressed as the coefficient λ of the formula $h = \lambda(Q^{1.802}/d^{4.854})$. The values of λ for the lead, brass, and copper pipes was found to be 0.00081 and for the galvanized-iron pipe 0.000977. Tests made with old pipes showed that brass, copper, and lead pipes were scarcely affected as compared with new pipes, while for old galvanized-iron pipe the value for λ was two to three times higher than for the new pipe. This formula used by Viesohn is not as convenient as the usual flow formula for plotting the relation of friction factor to the Reynolds number. The friction factor f from this formula is

$$f = \frac{k}{\left(\frac{vd}{\nu}\right)^{0.198} d^{0.052}}$$

so that it, like the Hazen-Williams formula, gives a slightly different curve for the f — (vd/ν) relationship for each pipe diameter.

ALTON C. CHICK.[37] So long as viscous forces are predominant and gravitational forces have negligible effect, it has been shown by many authors[38] that the friction coefficient f must be a function of the dimensionless ratio $vd\rho/\mu$ called Reynolds' number, or R, and that in smooth pipes this is the only criterion necessary for establishing similarity of flow.

The author has analyzed the data of many experimenters and has evaluated these on a common basis. It is a regrettable fact that many early experimenters did not include temperature observations, which would have opened to our use many more experiments.

The author has referred to experiments by Mr. John R. Freeman, and has used certain of Mr. Freeman's data. More concerning these experiments may be of interest. In 1892 Mr. Freeman organized and carried out what is probably the most complete series of experiments on the flow of water through commercial pipes ever yet made by a single experimenter. These tests covered a wide range of pipe materials and pipe sizes as well as many pipe fittings. Many times during the past 40 years Mr. Freeman undertook the publication of the results. Only two months prior to his death on October 6, 1932, the publication of these results was resumed, and the writer had recomputed much of the data on the scientific basis of Reynolds' numbers. Preliminary plottings show interesting results. The experiments on the smooth, seamless, drawn brass pipe cover a range of Reynolds' numbers from 175 to 880,000, and show a remarkable coincidence with the Stanton-Pannell curve in both the laminar and turbulent flow regions. The coefficient f appears to be entirely independent of the diameter of these smooth brass pipes. Preliminary plottings of data observed on the flow in new wrought-iron pipes indicate that the diameter does have an important effect on the coefficient f. The f-R plottings for the different pipe sizes form a family of curves that tend to converge in the vicinity of the upper range of the critical velocity and to diverge as the values of Reynolds' numbers increase. The larger the diameter of this new commercial wrought-iron pipe the nearer the f-R curve approaches that for smooth pipes; in other words, as the diameter of the pipe is increased so the relative roughness of ordinary commercial pipe is decreased.

In the case of pipes of the same geometrical form and with the same Reynolds number, but with different wall characteristics or different hydraulic radii, different values of the coefficient f are obtained. Therefore mechanical similarity of two flows is not assured through the equality of the Reynolds numbers.

If the relative roughness is known it becomes possible to determine in advance the pressure loss for a given flow.[39] However, many more experiments on the flow in pipes of known wall roughness are needed to determine a practical and useful relationship. It is hoped that the preparation of the data observed by Mr. Freeman will soon be completed and this information made available to others.

GEORGE I. RHODES.[40] The author has reduced to a common denominator much little-known but valuable information. Data coordinated by him were available in many forms, in metric and in English units, in the absolute and in the gravitational systems of units, and in some cases in mixtures of units and systems.

Equation [1] of the paper can be changed readily to the fundamental form

$$\frac{\text{Loss of head}}{\text{length}} = \text{Friction factor} \frac{\text{Velocity head}}{\text{Diameter}}$$

in which it is obvious that the friction factor has the same value whether loss of head, length, velocity head, and diameter are expressed in feet, centimeters, or any other measure of length, so long as they are all expressed in the same measure. Some investigators in reducing their results to a friction factor used an equation differing from the foregoing only in that radius is used instead of diameter, in which case the friction factor is one-half that of the author's curves; and other investigators prefer to use, in place of diameter, mean hydraulic depth, which has the distinct advantage of being universally applicable to a conduit of any cross-section, and the friction factor used by such investigators is one-quarter that of the author's data.

Reynolds' number is to most engineers a quantity as "ghostly"

as entropy. They have little concrete conception of viscosity. They do not appreciate that viscosity differs from modulus of elasticity in shear only in that angular velocity of movement is the inverse measure of viscosity, whereas angular displacement is the inverse measure of shearing modulus of elasticity. Perhaps some conception of Reynolds' modulus can be obtained by the following approximations applicable to certain fluids at ordinary temperatures. In the case of water Reynolds' number is 105,000 with a flow of 1 cu ft per sec in a pipe 1 ft in diameter and increases or decreases in the ratio of flow to diameter. In the case of natural gas or air, Reynolds' number is about 8000 with a flow measured in free gas or air of 1 cu ft per sec in a pipe 1 ft in diameter, which increases and decreases with the ratio of flow to diameter. In the case of steam at 250 lb pressure, Reynolds' modulus is about 18,000, with a flow of 1 lb of steam per minute in a pipe 1 in. in diameter and increases and decreases with the ratio of flow to diameter.

The author uses in his equations a definition of density that is correct in the absolute English system of units, but which definition is that of specific weight in the English gravitational system of units used in most engineering equations. He uses the symbol for density as specific weight in Equation [1], which therefore must be an equation in the gravitational system, but in Equation [2] he uses it as density, which equation therefore must be an equation in the absolute system. So long as density and viscosity are expressed in the same system of units, however, Equation [2] is correct irrespective of the system used. This double use either of the symbol for density or of the systems of units has apparently led to no confusion of results. It is pointed out only as an illustration of the pitfalls one encounters in attempting a work such as is summarized in this paper.

The author's statement that "at a Reynolds number of 1160 the friction factor should be independent of the pipe size regardless of its roughness" is far from proved. Curvature and irregularity are quoted by him as producing turbulence at Reynolds' numbers far below 1160, and in such cases with increased velocities sufficient to result in a Reynolds number of 1160, the turbulence must have been complete, with a resultant friction factor higher than that for viscous flow. The curves in Fig. 8 for used cast-iron pipes show friction factors well above those for viscous flow at Reynolds' number 1160. It is hard to conceive that the curve of friction factor against Reynolds' number, of any pipe however large or small or however smooth or rough, will intersect the theoretical curve for viscous flow at any one fixed point.

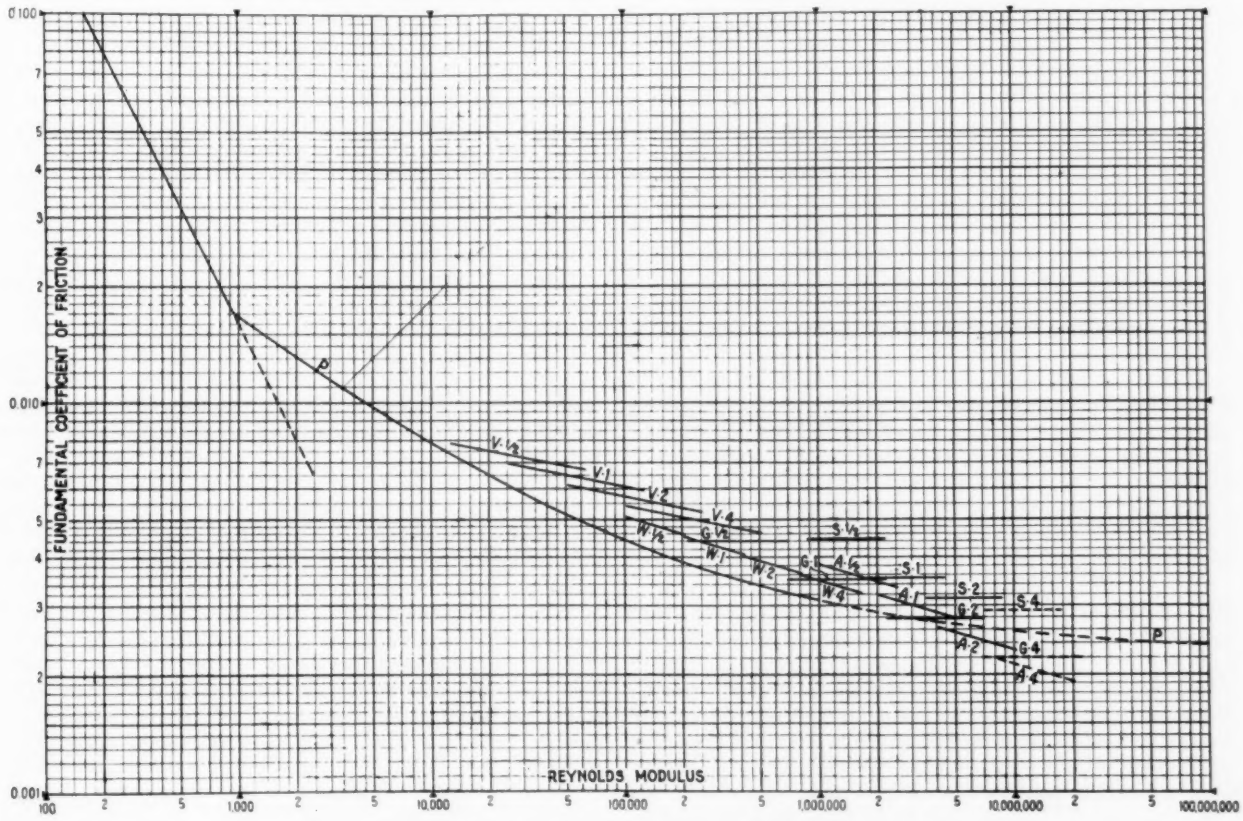

FIG. 17 COEFFICIENTS OF FRICTION IN COMMON PIPE-LINE FORMULAS

(Legend: *P*, oil lines from Heltzel, *Oil and Gas Journal*, June 5, 1930; *V*, ventilating ducts, velocities 4 to 20 fps, Marks' s Mechanical Engineers' Handbook; *W*, water lines, velocities 2.5 to 5 fps, Williams-Hazen formula, $C_w = 140$; *A*, air lines at 100 lb per sq in. gage pressure, velocities 40 to 100 fps, Fritche's formula; *S*, steam lines at 250 lb per sq in. abs pressure and 600 F, velocities 60 to 100 fps, Babcock formula; *G*, natural-gas lines at 40 lb per sq in. gage inlet pressure, 4 to 52 per cent pressure drop in 100 miles, Weymouth formula. Numbers following curve references are inside diameter in feet.)

To this extent the lower chart of Fig. 4 summarizing data on steel pipes is not fully justified.

Section VII of the paper compares the friction factors of formulas that have been used in the past. To supplement that table there is offered a chart (Fig. 17) of the coefficient of friction in common pipe-line formulas which shows the comparison between Reynolds' number and the fundamental coefficient of friction used in these various pipe-line formulas within the range of common practice. The dash lines in the chart show extensions beyond the sizes of pipe commonly used. In this chart the fundamental coefficient of friction is that required in the fundamental equation mentioned earlier in this discussion where the denominator of the right-hand half of the equation is the mean hydraulic depth—namely, one-quarter the diameter. Accord-

ingly the values of fundamental coefficient of friction in this chart are one-quarter of the values given in the author's paper. It should be noted that this chart is on a distorted scale, the length of one cycle of ordinates being twice the length of one cycle of abscissas.

Ordinary formulas, it would appear, take into account to some extent variations in the coefficient of friction and are in form suited for a convenient computation. There is some doubt if it is worth while to take these variations into account more accurately on account of vagaries in performance of pipe lines not fully explainable.

It has been found of great help in evaluating charts of coefficient of friction against Reynolds' number to have appear on the chart a portion of the line for viscous flow. This line will intersect the line of Reynolds' modulus having a value of 1000 at a friction factor of 0.016 or 0.032 or 0.064, depending upon whether the fundamental formulas used are based on hydraulic depth, pipe radius, or pipe diameter, respectively.

Pipe lines as actually installed do not perform as closely to expectations as might be inferred from the author's statements as to the accuracy of his curves. Some pipe lines are as much as 25 per cent below par when measured by the friction factor and some are 25 per cent above par. Tuberculated iron water conduits are so much below par that mere reduction in diameter from the tuberculation fails completely as an explanation of low capacity. Roughness is undoubtedly an important factor, but there is little understanding of the manner in which it works its nefarious purpose. Its effect may be generally explainable as that of a series of shallowly projecting diaphragms, which effect if applied quantitatively does at least account for the behavior of tuberculated pipes. It is hoped that this diaphragm or orifice theory may be fully developed because it seems to offer interesting possibilities with pipes of controlled smoothness. Research concerning the effects of roughness is much needed, and it will certainly be well worth while if as a result we can specify and control roughness to the end that all pipe lines are as good as the best now built, namely, 25 per cent above the average, or even better in the case of very large lines.

R. J. S. Pigott.[41] It may be of interest to indicate the occasion for the analytical research undertaken by the author. Much of the work in which both the author and the writer are engaged involves flow of liquids and gases, and also in a great many cases the flow of mixtures, on which there are few experimental data. As a preliminary to the undertaking of the more difficult problems of mixed flow, a study was made on the subject of purely liquid or purely gaseous flow.

The one point that struck us most forcibly was that in practically all previous dissertations on the subject the theories and formulas were predicated only on a portion of the available data, with the result that the formulated results of many writers differ in form to some extent, but give only slightly differing results. In many cases the reasoning employed to reach these formulated results shows very wide divergences due to the recorded data investigated in each case. We therefore thought it would be desirable to recalculate on the dimensional basis all of the available data so as to show the range of variation and the trends very much more authoritatively.

In his investigations the author soon found that much of the presumably useful data on the subject were lacking in one or more of the required factors such as accurate knowledge of diameter, roughness, and viscosity. As a result, much of the data which have been reported could not be used because accurate information on one or more of these factors was missing or incomplete. However, the remaining mass of data was very much greater than had been correlated before by any one investigator, and it is certainly clear from the author's results that at last we are in a fair position to formulate with some decision the effect of roughness, which has hitherto been largely neglected except by purely empirical methods such as exemplified in the Williams and Hazen well-known tables.

After studying the paper, it becomes obvious that many of the friction-factor curves offered by earlier investigators have shown marked differences to those obtained in this paper, because the roughness was not constant for the different sizes and kinds of pipe for which the curves were drawn.

Another point rather clearly brought out is that all values for the friction factor in the turbulent region exceeding the value at the critical point must be incorrect; in general, it may be noticed that such high values are only found with rough pipe, and in practically every case there is evidence that the diameter was not correctly obtained. When such results are corrected to the true diameters, friction factor always remains under the value at the critical point in the $dv\rho/\mu$ plot. It would seem that this conclusion is of some importance, inasmuch as it insures that the friction-factor lines for all roughnesses of pipe, from perfectly smooth brass to perfectly rough materials, must pass fanwise through the value at the critical point. This differs from the assumption made in the Williams and Hazen formulas and many others of similar type, that the friction-factor curves for varying degrees of roughness are all parallel. This latter assumption has resulted in such anomalies as assigning higher roughness to small brass pipe than to cast iron.

These points are covered more fully in the writer's paper on "The Flow of Fluids in Closed Conduits," delivered before the National Process Meeting in Buffalo, June, 1932. This paper should be regarded more or less as a continuation of the investigation covered by Mr. Kemler's paper. It is expected that the work will be continued to collect the material on loss of pressure due to bends, valves, and other fittings. We are also expecting to carry out some research experiments on the flow of mixtures of gas and liquid in both horizontal and vertical pipes. This problem is extremely important in the investigation of the behavior of flowing oil wells, air lifts, and similar conduits carrying mixed fluids. As yet, we have been unable to find a strict physical basis for the variation of the friction factor with Reynolds' number, but the investigations, so far as they have gone, indicate that a mathematical investigation of the shape of the velocity traverse in a pipe will give the cue for the physical meaning of the Reynolds criterion.

Benjamin Miller.[42] This paper gives the impression that the scientific basis for analyzing the results of experiments on the flow of fluids was originated by Reynolds and that Reynolds also discovered that there are two types of fluid motion. Such an impression would be far from the truth. It is not the purpose of this discussion to minimize the contribution of Reynolds, but rather to place it in its proper light.

As Stanton and Pannell point out in reference 4 of the paper, Newton, Stokes, and Helmholtz preceded Reynolds in the theoretical treatment of the problem, so that Reynolds cannot be said to have developed the equations for dimensional homogeneity and dynamic similarity. Bingham, in the preface to his book "Fluidity and Plasticity," says, "It was in 1842 that viscous flow was first differentiated from hydraulic flow," and gives credit on pages 35 and 36 to Darcy as "probably the first to distinguish clearly between the two régimes."

The importance of Reynolds' work lies in his experimental demonstration of the theories which had been put forth before

[41] Staff Engineer, Gulf Production and Pipe Line Companies, Pittsburgh, Pa. Mem. A.S.M.E.

[42] Henry L. Doherty & Co., New York, N. Y.

and in his determination of the region in which the two régimes overlap. He was also the first to attempt to give explicit form to the relation expressed by $f = \phi(Dv\rho/\mu)$, but subsequent experiments showed that his formula is incorrect.

Why did two centuries elapse between the publication of Newton's theoretical deduction of the criterion for similarity and the publication of Reynolds' experimental verification? And why, after another half century, do we find many engineers unwilling to accept it and use it in their practice? And, on the other hand, how does it happen that it is being used by other engineers? Any answers must be speculative, but such speculation is useful as well as interesting, since it illustrates the conflict between abstract philosophy and concrete empiricism, and the engineer should strive to use the fruits of both.

The writer's answers to these questions involve a subject which is not even mentioned in the paper under discussion—the hydrodynamics of ideal fluids. Although the hypotheses of Newton lead to equations for motion of viscous fluids, the hydrodynamics of the eighteenth century was concerned exclusively with ideal fluids. The simplest experiments showed striking differences between the behavior of real fluids and the predicted behavior of ideal fluids. This was not unknown to the theorists; Hatschek, on page 6 of his book, "The Viscosity of Fluids," quotes Bernoulli: "I attribute these enormous differences for the greatest part to the adhesion of the water to the sides of the tube, which adhesion can certainly exert an incredible effect in cases of this kind." This was published in 1738.

Engineers could not wait for mathematical physicists to develop the complete theory, but while they developed empirical formulas they hoped that the theory would be developed. In 1804 Prony published the results of his researches; from his work Hatschek quotes: "It is regrettable, and even astonishing, that the celebrated Euler, who in the course of his immense labors has often turned his attention to physico-mathematical problems and their practical applications, should not have endeavored to treat the theory of liquids by taking into account the cohesion of the molecules and some kind of friction; even if he had introduced these resistances into the analysis in a purely hypothetical form, it would be interesting to know how he envisaged their effect; but I do not know of any paper by him where they are mentioned."

In 1813 Girard advanced a theory strikingly similar to some heard today. He assumed that there were two kinds of resistance: one, "the force with which all the molecules of the perimeter adhere to the liquid layer which envelops and wets the wall," is simply proportional to the velocity, and would be the only one if the wall were absolutely smooth; its asperities, however, are reproduced in the liquid film and give rise to turbulence, which produces a second resistance term containing the square of the velocity.

In 1823 Navier published the general hydrodynamic equations for viscous fluids. He did not integrate them correctly for flow through a cylindrical tube. This was done later by Stokes (1842).

Before the theoretical development of the formula for resistance in viscous flow was available, Hagen and Poiseuille had started their experimental attack on the problem. The latter's work especially was so elegant and complete that the problem of viscous flow was practically solved by the middle of the last century. Further theoretical investigations were made by Wiedemann (1856) and Hagenbach (1860), but from the time of Poiseuille the main emphasis has been on applications.

By this time we may imagine that the hydraulic engineers were not very hopeful of getting help from the physicists. They had the accumulated experience of more than a hundred years of practical work, whereas the physicists had only just discovered the laws of viscous flow. The viscous-flow laws were of no use to the hydraulic engineers, since they were not working in the viscous régime, and no one knew how far the viscous régime extended. This was the situation when Reynolds attacked the problem. Reynolds found the common limit of the two régimes, and offered a law for the turbulent régime of the form $f = aR^n$, in which f is the coefficient of friction, R the dimensionless group we call now Reynolds' number, and a and n constants; a depends on the dimensions, and for n Reynolds gave —0.277.

It is not surprising that engineers did not immediately abandon the formulas which they had used so long. It is not even surprising that most of them did not consider the work of Reynolds to have any application to their problems. As far as hydraulic engineers were concerned, Reynolds' work might have been forgotten. That it has finally gotten recognition from engineers concerned with the flow of fluids through pipes is probably due to the work of men engaged in a seemingly unrelated field—aviation.

The designers of aircraft had to know more about the resistance to relative motion of solids and fluids. After empiricism had brought aviation into existence, philosophy was called in. This was probably because if the factor of safety were too great the plane would not leave the ground, while if it were too small it would return too suddenly. At any event, reliance had to be placed on models. To use models intelligently required the principle of dynamic similarity, and the application of the principle of dynamic similarity to the problem of surface friction was suggested by Rayleigh in the report of the British Advisory Committee for Aeronautics for 1909–1910. And so it came about that the classic experiments of Stanton and Pannell were carried out, not in a hydraulic laboratory, but in the Aeronautical Department of the National Physical Laboratory of England, the object being "to confirm the existence, under certain conditions, of the similarity in motions of fluids of widely different viscosities and densities which has been predicted, and further, by extending the observations through a range in the velocity of flow which has not hitherto been attempted, to investigate the limits of accuracy of the generally accepted formulas used in calculations of surface friction."

The writer's excuse for the presentation of this discussion of the historical development is his feeling that something of the sort should appear in a paper with this title.

The remainder of this discussion is concerned with the deviations in the paper from the principles and results given in Stanton and Pannell's paper. In the first place, it should be pointed out that the use of the principle of dynamic similarity requires that certain assumptions be made, but those assumptions must be made on other grounds, and they remain assumptions even though limited experiments show that the relations derived with their aid describe the facts fairly well. The introduction of other assumptions must then be justified by experiment also. In this case the assumption is that the resistance depends only on the linear dimensions of the surface, and on the velocity, density, and viscosity of the fluid. From these assumptions may be derived the relations given in Equations [1] and [2] of the paper. (In consistent units, but as has been pointed out the units used in this paper are not consistent, in that pound is used as the unit of mass and force.) The use of the term diameter implies that geometrically similar surfaces are being considered, but the geometrical similarity must extend to those irregularities in the surfaces which constitute roughness.

Classification of pipes as to material and size is therefore equivalent to making the additional assumption that roughness is determined by material and size. Experiments to prove this are lacking, despite the curves presented in this paper. There is no reason to believe that steel pipe, for example, must be rougher

than brass pipe, nor that all steel pipes of the same internal diameter must have the same roughness. To accept curves such as shown in this paper is to deny the possibility of progress.

The writer believes that it would be far better to use the relation between Reynolds' number and the friction factor for smooth pipe as determined by Stanton and Pannell (and extended by Nikuradse, it appears, though the writer has not yet had the opportunity to study his results) as the basis for design, making such allowances for the difference between the smooth pipe and the actual pipe which must be used as experience and tests indicate may be necessary. There seems no reason to believe that commercial steel pipe cannot be made geometrically similar to the brass pipe used in Stanton and Pannell's tests; if designs are based on smooth pipe, the cost of roughness may be evaluated, and there will be a definite incentive to manufacturers to produce smooth pipe.

The few recent studies which have been made on pipe which is not smooth have indicated that for these also the general law connecting Reynolds' number and the friction factor given by Lees holds: $f = a + bR^n$.

If further tests should show that this law is generally applicable, it will require only a few tests to determine the relation for any particular kind of pipe. This has been pointed out by Parry, in the English *Electric Journal*, Vol. 1, No. 4, October, 1920, p. 146; Parry indeed suggests that for all pipes the curves for f against R should intersect the viscous-flow curve in a point, thus anticipating the notion of maximum friction factor brought out in this paper. However, there are indications that for very rough pipe the curve of f against R will rise after reaching a minimum.

The custom of plotting the curve of f against R on double logarithmic charts should be discouraged. On such a chart the curve is almost straight over a short range, and the temptation to make it straight is great. The curves for smooth pipe have been drawn as straight lines in this paper, despite the fact that one of the most important parts of the work of Stanton and Pannell was to prove that Reynolds' index law did not hold.

The introduction of the concept of mean hydraulic radius requires making an assumption which has not so far been proved. Geometric similarity must be discarded if the mean hydraulic radius is to be used. The use of the mean hydraulic radius is an attempt to combine size and shape, and it is quite certain that this can lead only to rough approximations. In cases in which mathematical solutions cannot be obtained, it is best to make model experiments.

The writer would point out that the results of the early experimenters are not necessary to prove the theory and that numerical values obtained by analysis of the results on all but smooth pipes must be used with a great deal of caution.

ALEXEY J. STEPANOFF.[43] One of the reasons why engineers are somewhat reluctant in adopting the modern method of calculation of the pipe flow, based on the scientific principle of dynamic similarity, is that the data available seemed scattered and unrelated. The work accomplished by the author is just as important as the experiments themselves. It is through investigations like this that the results of research find their way to practical application, because it is by the study and comparison of the data obtained by different experimenters that general conclusions can be drawn. It was gratifying to see that the scattered data on pipe flow were found to be consistent and fit into the picture outlined by great investigators. The division of the test results by the author into groups according to the pipe roughness seems very logical and greatly simplifies the problem.

The Reynolds discovery was not appreciated for more than thirty years, for the following reasons: First, at the time of discovery there were no real problems of pumping viscous liquids. Then, the knowledge about viscosity, its properties and measurement, was meager among practical engineers. This is true to a smaller degree even now. Further, the existence of the two modes of flow was known before Reynolds, but he showed the existence of critical velocity and established in an experimental way that both modes of flow were functions of what is now known as Reynolds' number.

Contrary to the author's statement, Reynolds did not test his equation of flow for dimensional homogeneity using an exponential formula with exponent varying from 1.75 to 2. It was not until Lord Rayleigh in 1911 and Stanton in 1914 took up fluid friction in the academic sense that Reynolds' discovery was presented in a form suitable for use by practical engineers.

One of the important things we learned about pipe flow is that all the exponential formulas are both theoretically and in practise wrong. According to the theory, the exponent for the turbulent flow should be 2. In practice it was found that different fractional exponents advocated from time to time cover only different portions of the function to be determined experimentally.

Another important result of the theoretical study of pipe flow is that the resistance of the flow is a continuous function of Reynolds' number only when the flow is dynamically similar, the geometrical similarity being one of the requirements. Hence it should not be expected that the data obtained with circular pipes would check with that for any other form of section, and since roughness does not follow geometrical similarity, a series of lines are obtained instead of one depending on the surface conditions of the pipe. On account of flatness of the curve representing function in Equation [2] for turbulent flow, the results obtained with other than circular sections do not differ much from the pipe data, while for viscous flow the difference is quite material. As a result of dynamic similarity, the velocity distribution across the pipe section is similar for the same values of the Reynolds number. The ratio of the mean to the maximum velocities varies from 0.5 for the viscous flow to over 0.81 at high Reynolds numbers. Anything that disturbs the velocity distribution destroys dynamic similarity, and the value of the function in Equation [2] will be different. This explains why the data obtained with curved, moving, or revolving pipes do not agree with the results at normal conditions. The geometrical similarity as to the length of pipe, especially the form of approach to the observed length in the case of laboratory experiments with comparatively short pipes, was found to have noticeable effect on the observed loss of head.

Having established the function represented by Equation [2] for circular pipes, it is possible by reversing the procedure to use the results for measurement of viscosity when all other means fail, as in the case of air-water mixture. By observing the friction loss for a given pipe, the value of Reynolds' number, and hence the kinematic viscosity, can be determined. The writer experimented some years ago with air-water mixture and found that the friction loss depends not only on the air-water ratio, but on the way air is distributed in water.

Most of the experiments on pipe flow were performed with commercially clean fluids. Presence of foreign matter like gas in oil, or sand and air in water, affects greatly the friction loss, the magnitude of the head lost depending on whether the sand or air is rolled along the pipe or carried in suspension. The friction loss in the first case is considerably greater than in the second. Some data on the sand transportation in pipes will be found in Trans. A.S.C.E., Vol. 57, p. 400, 1906.

From this review of the flow problem in its simplest form, with constant velocities and circular cross-section, one can see that calculation of the friction loss in pipes requires a great deal

[43] Designing Engineer, Byron Jackson Company, Berkeley, Calif. Mem. A.S.M.E.

of knowledge and judgment, and, we quote Gibson, "The engineer who predicts to within 10 per cent the discharge from a pipe under given pressure conditions has every reason to be satisfied with his choice of constants." Mention might be made of the extraordinary difficulties in the calculation of friction losses in hydraulic machinery—centrifugal pumps and hydraulic turbines; where the form of channels varies greatly from inlet to outlet, the velocities vary from section to section, and part of the water path is curved and revolving. In addition to friction losses, there are shock losses, and there is no way to measure even the combined loss. Thus separation of the hydraulic losses and evaluation of different items in a pump or turbine are more or less arbitrary.

The author's statement of the principle of dimensional homogeneity is not accurate. Quoting Buckingham,[6] the principle requires that "all the terms of any correct and complete physical equation must have the same dimension." "Complete and correct" in this statement implies that the subject to be investigated should be sufficiently known to establish what quantities should be included in the equation.

Any mistake in this respect would result in a wrong conclusion and the blame might be put on the dimensional analysis, while all the dimensional analysis does is that it enables one to reduce the form of the equation to the extent that the relationship between the quantities involved becomes more explicit. The equation tested for dimensional homogeneity may have several terms, like Bernoulli's equation, which may not be equal. The dimensional homogeneity of different terms only means that length may be compared with length, mass with mass, etc.

The author does not follow his own notation; the list of symbols gives m for the mean hydraulic radius (English notation), while r is used in the text.

The writer wonders whether the long list of the test data given by H. Hughes and A. Safford in their book on hydraulics, and references attached to Williams and Hazen tables, have been overlooked by the author. It is hardly possible that these data turned out to be unreliable. Also, some interesting test results on circular pipes and annular sections will be found in Mitteilungen des Instituts für Strömungsmaschinen der Technischen Hochschule Karlsruhe, heft 2, V.D.I. Verlag, Berlin, 1932.

The writer hopes that the author will keep his promise to append this paper with some more test data which may be made available since the issue of the preprint of this paper.

R. W. Angus.[44] This paper is valuable in calling attention again to the value of the Reynolds number in estimating the friction loss in pipes. The Reynolds number does not seem to have gained the place in practise that the theory would indicate it should occupy, and this is probably because it does not give all the information with regard to friction in pipes.

If the pipes are absolutely uniform as to their roughness, then the Reynolds number enables one to determine accurately the friction loss irrespective of the nature of the fluid flowing, but it is actually impossible to have pipes of different sizes of the same relative roughness, and this fact largely neutralizes the conclusions that one would naturally draw.

In looking at Fanning's table for the values of f, one is immediately aware of the fact that Reynolds' law has not been followed, and this is usually explained in the very simple way of saying that the pipes are of different relative roughness—a conclusion which may or may not be true.

The author has not included in his results information contained in a paper presented by F. Carnegie, Proc. Inst. M.E., 1930, Vol. 1, p. 473, in which a number of experiments have been given on the flow of steam in pipes 2 in., 6 in., and 8 in. in diameter, with steam velocities from 27 to 146 ft per sec. The steam pressures were in the neighborhood of 200 lb and of 66–88 lb, with about 100 F superheat in most cases. In this paper the Reynolds number and the corresponding friction factor have been determined by Mr. Carnegie, the coefficient of the viscosity of the steam being taken from a paper by Speyerer and reported in the *Z.V.D.I.*, 1925, Vol. 69, p. 747.

It would be helpful, in connection with this important subject, if tables of viscosity of different fluids were available in convenient form.

K. M. Peters.[45] The writer would like to offer some data on the mean hydraulic radius as a criterion for flow in the turbulent region. Using the mean hydraulic radius as a basis of comparison, the curves in Figs. 18 and 19, were recalculated from published

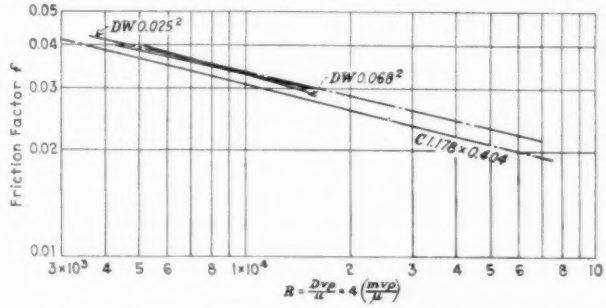

Fig. 18 Flow in Rectangular Sections

(Legend: C = Cornish; DW = Davies and White. The broken-line upper and lower curves are for smooth circular pipe.)

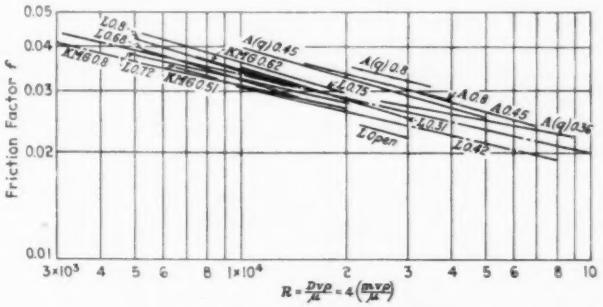

Fig. 19 Flow in Annular Sections

(Legend: A = Atherton; q = air used as fluid; L = Lonsdale; KMG = Kratz, Macintire, and Gould. The numbers give the ratio of core diameter to shell diameter. The broken-line upper and lower curves are for smooth circular pipe.)

data taken from the references given in the summary of tests herewith. In order to make a direct comparison with Mr. Kemler's results, the equivalent diameter was used in these curves, which have been marked similar to his.

The tests on rectangular pipes indicate that the friction factor is the same as that obtained from tests on circular pipes. This could be anticipated from the fact that the dimensions were varied and the same surfaces were kept in contact with the fluid. Because of the similarity in shape, the roughness effect should compare in magnitude to that for a circular pipe.

Annular spaces offer quite a wide variation in friction factor. Some noteworthy conclusions can be drawn from this data, however. Tests by Lonsdale marked open, 0.31, and 0.75; 0.42 and 0.68; 0.72 and 0.8 were made with 2.520 cm, 1.895 cm, and 3.972 cm shell diameters, respectively. The open pipe

[44] Professor of Mechanical Engineering, University of Toronto, Toronto, Ont., Canada. Mem. A.S.M.E.

[45] Senior in Mechanical Engineering, University of Pittsburgh, Pittsburgh, Pa.

shows a much lower friction factor than the shell using a small core, which in turn shows a lower value than that for a large core. A similar relation exists for the other two pipe sizes tested by Lonsdale. The reason for this is that the relative roughness is increasing as the core size increases and produces a higher f. Kratz's experiments follow this tendency, with the exception of tests using a large core, which give lower values. The condition of the outside of the core could, however, account for this apparent discrepancy. Atherton's tests correspond to Lonsdale's, but his values cannot be given much weight because of the inconsistency of his data, as can be seen by an examination of his paper.

These data show that the friction factor for open pipes is very near the value for circular pipes. For annular spaces the friction factor will be appreciably higher; the magnitude of this increase depends upon the ratio of core diameter to shell diameter and on the roughness of the pipe itself.

Summary of tests on annular and rectangular brass pipes (water is the fluid used, except that the Lonsdale tests were with air and water and the Kratz tests with water and $CaCl_2$): Annular: "Fluid Flow in Pipes of Annular Cross-Section," by Atherton, Trans. A.S.M.E., Vol. 48 (1926), p. 145. "Flow of Water in Annular Spaces," by Lonsdale, *Phil. Mag.*, Vol. 46, p. 163. "Flow of Liquids in Annular Cross-Sections," by Kratz, MacIntire, and Gould, Univ. of Ill. Eng. Expt. Bul. No. 222. Rectangular: "Flow of Water in Rectangular Sections," by Cornish, Proc. Roy. Soc., Vol. 120, p. 691. "Flow of Water in Rectangular Pipes," by Davies and White, Proc. Roy. Soc., Vol. 119-A (1928), p. 92.

Adolf A. Meyer.[46] The writer was interested in comparing the information presented by the author with the established formulas for computing flow in pipes.

In Fig. 20 the author's relation curves between Reynolds' number and friction factor f for brass pipes are replotted. In addition, similar curves are added based on computed values according to the formulas of Bazin, Manning, and Kutter. Whether these formulas should be applied for flows in pipes is not questioned here, the interest being based on the fact that they have been used and are still being used extensively for the solution of problems of flow in pipes. Coefficients of friction n for Kutter and Manning and m for Bazin for smooth new pipes, corresponding to the condition of brass pipes, have been used.

The resulting curves computed after Bazin and Manning are straight lines as expected, as in both these formulas the loss of head, from Chézy's fundamental relation, varies with the square of the velocity. As f is expressed as a function of $\Delta h/V^2$, there remain for a given diameter only the constants which plot as a straight line. According to Kutter's formula, the shape of the curve is not a straight line. For the small diameter pipes plotted in Fig. 20, the curve drops within the range of the smaller Reynolds numbers similar to the results given by the author for brass pipes, but with increasing slopes they show a tendency to extend as a straight horizontal line. The difference between the curves according to Bazin and Manning on one hand and Kutter on the other hand is due to the fact that in Kutter's formula the coefficient c also is a function of the slope.

[46] Pennsylvania Water and Power Company, Baltimore, Md.

It is interesting to note that for varying diameters of pipes the friction factor varies. If we refer to the author's Fig. 4, we notice a similarity, as the small-diameter pipes show higher friction factors than the larger pipes for identical Reynolds numbers. Evidently from lack of data the author did not carry out this differentiation of pipe sizes in the other diagrams presented.

Looking over the successive diagrams, it will be noticed that with increasing roughness more and more groups of tests made with the same diameter pipe approach the horizontal straight-line curve, or, in other words, show closely the same relation between the loss of head and velocity as do the established formulas. The general picture of all the data presented still apparently shows the downward trend, but the question raised

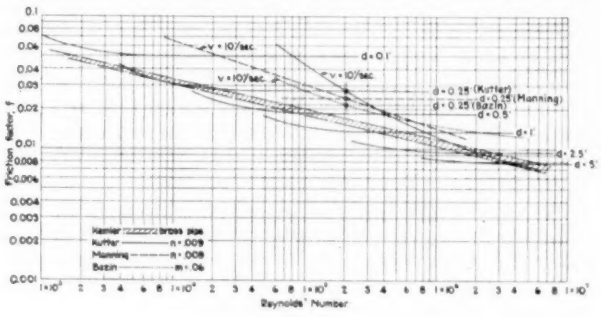

Fig. 20

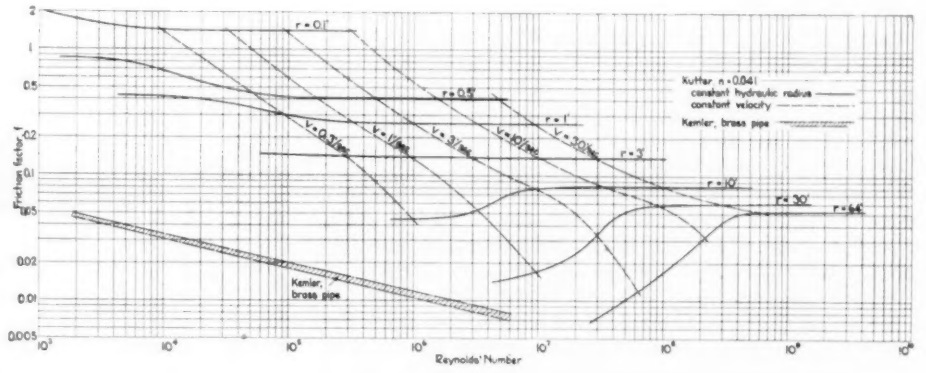

Fig. 21

is whether this trend is due to actual decrease of the friction factor or due to the accidental fact that with increasing Reynolds numbers more and more tests plotted were made on larger pipe sizes to correspond with the high velocities required for the higher Reynolds numbers. When plotting curves of equal velocities for pipes with varying diameters, the downward trend of the velocity curve is clearly apparent in Fig. 20.

What aroused the interest of the writer in the author's paper was above all its application to backwater computations. If for turbulent flow the friction factor would decrease under all conditions with increasing Reynolds numbers, then backwater computations based on Kutter's formula would obviously be wrong.

To present this problem more clearly, Fig. 21 was drawn up. The relations between Reynolds' numbers and the friction factor f computed according to Kutter's formula were plotted for different hydraulic radii between $r = 0.1$ and $r = 64$ and for an $n = 0.041$, which factor was taken from an average figure found in a river on which the writer had occasion to investigate backwater.

Let us assume that during a season of high flow a stretch of

river with a mean $r = 64$ and a mean velocity of 30 ft per sec is observed. The Reynolds number for this flow would be 6×10^6, the friction factor $f = 0.051$. Suppose that by some obstruction downstream the water surface during low flow would be raised to such an elevation as to give the river stretch the same mean $r = 64$ with the velocity reduced to 3 ft per sec. With the Reynolds numbers now ten times smaller, we should expect, according to the data as presented by the author, a friction factor larger than 0.051. According to Kutter, the friction factor is reduced to 0.011.

We have had the opportunity to check computed backwater in the field after ponding took place. The actual observation confirmed the values computed in accordance with Kutter's formula within a very close range. Reference is here made to an article by W. D. Myers on "Comparison of Computed Backwater Profile With the Actual Observed Profile," published in the 1929 report of the Hydraulic Power Committee of the Pennsylvania Electric Association.

Referring to Figs. 13 and 14 of the author's paper, "Flow in Artificially Roughened Pipes," we notice there a few tests which show an upward trend, or, in other words, show the loss of head varying to a power greater than 2.

The suggestion is offered that the information presented by the author be rearranged in a three-dimensional system by plotting Reynolds numbers in one direction, pipe diameters or velocities in another, and the corresponding friction factors in a third. This would show a topographic picture of the friction factor from which the interrelation of the three factors involved could be more clearly understood. With the information as now represented, a warning might be placed not to depend uncritically on the decrease of the friction factor for increasing Reynolds numbers when using the same size pipe.

A. B. Cox.[47] The proposal to establish upper and lower limits for the value of the friction factor, as suggested in the paper, should be a valuable contribution both to theory and practise. The author's curves do not show the points plotted which determined them. Curves with data points plotted are nearly always much more preferable to those without them. This is all the more true here, because some of the methods used by some experimenters for determining the critical flow limits are questionable.

L. Schiller.[48] This collection of voluminous data, particularly on the flow in rough pipes, is especially valuable to us in Europe because it contains a large number of American experimental results which are not generally available to us here. The value $f = 0.054$, for the pipe diameters customarily used and neglecting pipes of extreme roughness, appears to indicate a definite upper limiting value. One must be absolutely clear about the fact—and this is not definitely stated in the paper—that for equal "absolute roughnesses" a further diminution of the diameter will result in higher f values.

As regards the relation of the critical f value, $f = 0.054$ to the "absolute critical number 1160," the following should be pointed out. According to the designation of the author, $R = Dv\rho/\mu$, the critical number is not 1160, but 2320. To this value belongs $f = 0.038$, not 0.54. With regard to the resistance law for *smooth* tubes one may say today that it has been confirmed to a value of $R = 2 \times 10^6$ within 1 per cent, by the recent experiments at Leipzig and Göttingen (Hermann, Nikuradse)[49] which check each other. The resistance law as expressed by Hermann is $f = 0.00540 + 0.396R^{-0.300}$

As to the question of *rough* pipes, there is lacking any experimental proof of the law of similarity. A rigid proof may be made most easily with relatively coarse systematically arranged roughnesses. We in Leipzig have carried out experiments on two tubes of 5 and 10 cm diameter with regularly spaced reducing flanges built into them. In these experiments complete similarity has been maintained as far as it may be attained practically (test to 0.03 mm). The similarity law has been confirmed to within 2 to 3 per cent.

Author's Closure

The comments of Mr. L. Schiller are very interesting, as they give the European opinions on this subject. His comments relative to the experimental proof of the law of similarity as applied to rough pipes are most welcome. The fact that complete similarity has been maintained in so far as it may be attained practically gives the necessary assurance that tests on rough pipes made with one fluid may be applied to another fluid. While this law has been practically applied, this is apparently the first series of tests to definitely establish that the law held.

The question raised by Mr. Baumeister is the final result in which the practicing engineer is interested. Until it is better understood just how roughness affects pipe flow, it will be impossible to make any rigid statements as to the values that should be used. The coefficients such as Mr. Baumeister gives have to be used with care, since it amounts to saying the roughness has the same effect at all Reynolds numbers. As long as there is a viscous film on the pipe, the effect of roughness will necessarily be less than when this film disappears. Since the viscous film varies with the Reynolds number, curves of the type such as Mr. Pigott gives in his paper seem to be a reasonable solution. Fig. 22 and Table 5, which are taken from the data in Fig. 1 and Table IV, respectively, of Mr. Pigott's paper, illustrate the type of curves just referred to. These curves which Mr. Pigott gives are the best information available at the present time on friction factor for rough pipes.

The question as to whether the friction factor depends upon Reynolds' number only, and is not influenced by the diameter (assuming the roughness effect the same) or velocity, as brought out by Mr. Spitzglass and Mr. Meyer, is an important consideration. The results on brass pipes for different fluids and pipe

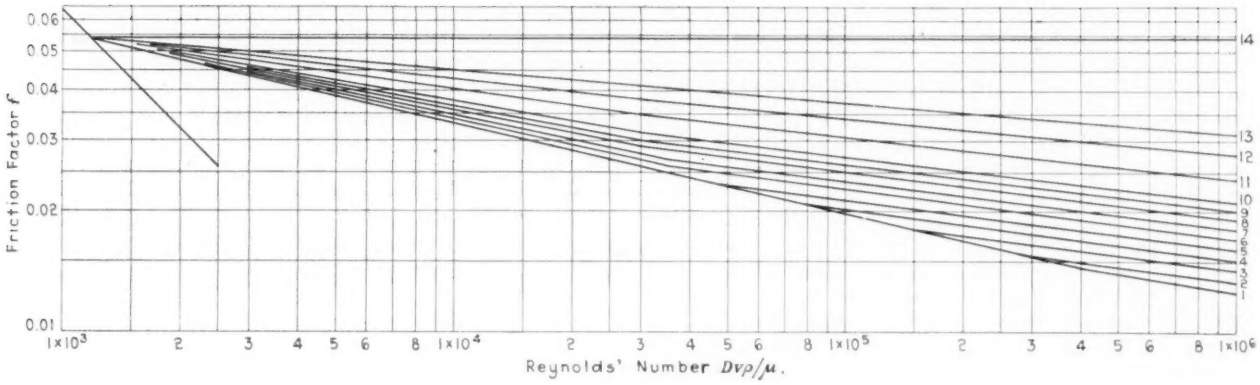

FIG. 22

sizes indicate that the friction factor depends only upon the Reynolds number for smooth pipes. The suggestion of Mr. Meyer that a three-dimensional plot be made is very interesting, but to obtain reliable results a series of tests with this as an objective would have to be made, otherwise variations in roughness and viscosity might influence the results.

Mr. Stepanoff and Mr. Pigott have brought out the point that the velocity distribution is an important factor. It seems to the author that a study on rough pipes which would give data on the velocity distribution, friction factor, and Reynolds' number would add much to our understanding of the behavior of rough pipes. A microscope study of the pipe surfaces should be made to see how it influences the velocity distribution. Such a study would have to be very complete in order to give conclusive results.

The author recognizes that the field of viscous flow has only been touched upon in the paper, but the limitation that had to be placed on this research problem and the fact that the viscous law has been generally accepted are the reasons for its omission. Most of the emphasis was placed on turbulent flow, since it has the larger field of application and is the field about which we have a limited knowledge. The comments of Prof. Glen Cox, therefore, add welcome information in this field.

The comments of Mr. A. C. Chick concerning Mr. Freeman's results are of considerable interest. An examination of the summarizing curves for steel pipes will show that Mr. Freeman's test results fall almost on the average curve for each case. His tests cover the entire range of pipe sizes and were apparently made with exceptional care. The making available of the complete data should be a valuable contribution to the literature.

The historical development of hydraulic flow equations as given by Mr. Spitzglass in his paper, "Similarity: Limitations in Its Applications to Fluid Flow,[50] together with that given by Mr. Miller, gives a brief outline of the historical background of this paper.

Mr. Miller's criticism of the use of various curves for different size steel pipes is misleading. There is reason to believe that ordinary steel pipe is rougher than brass pipe because of the difference in method of manufacture. There is no better proof of this fact than the test results given in the paper, which show this to be so, and in the final analysis there is no other proof possible. The author would agree to a statement that it is possible to make steel tubing as smooth as brass pipe, but it remains that it is not usually made that smooth. While there is a definite saving possible in using smooth pipes because of the lower friction losses, the pipe usually cannot be kept in a smooth condition when subjected to abrasive or corrosive action. Under such conditions the pipes soon become rough, and the extra price that must be paid for smooth tubes cannot be justified on a saving in power costs alone.

It is true, as Mr. Rhodes brings out, that the making of all the curves to pass through the value of Reynolds' number equal to 1160 has no proof. However, with the qualifications placed upon it there seems to be some justification for using it. These qualifications are that the actual diameter be used and that the roughness be of an order of magnitude such as not to cause contraction and enlargement losses. A study of rough pipes, as outlined before, would do much to clear up this theory.

The curves of Mr. Peters give additional data on the mean hydraulic radius as a criterion for flow in the turbulent region.

The suggestion of Mr. A. B. Cox that the points for the curves should be plotted is an impossibility, as this would have required about 300 figures to show accurately the data for all of the curves.

There has been some confusion concerning the value $R = 1160$ as given by Schiller. The value as obtained by Schiller was 580 on the basis of using the radius in Reynolds' number. The value of Reynolds' number based on the diameter would then be 1160, or the value used in this paper. In all cases the use of the term Reynolds' number in this paper means $Dv\rho/\mu$.

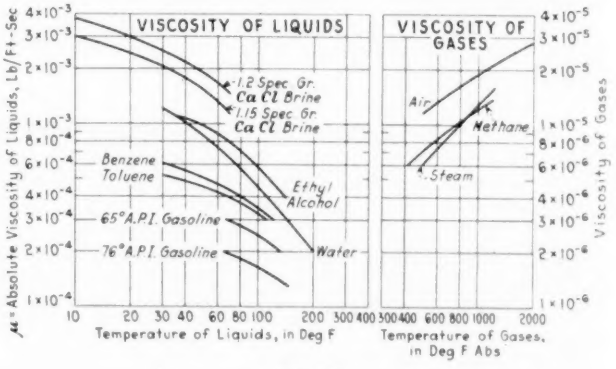

FIG. 23

Curves of viscosity as suggested by Mr. Angus are given in Fig. 23. The data on viscosity were taken from the Handbook of Chemistry and Physics, the Smithsonian Physical Tables, and *The Petroleum Engineer*, November, 1932, p. 26. The data given by Mr. Angus and Mr. Van der Pyl have not been replotted for reasons of economy. The references referred to by Mr. Stepanoff were not used because the complete test data were not available.

In conclusion, the author wishes to express his appreciation for those who have added their experiences and comments. It is hoped that this paper will indicate the fields of research needed to increase our knowledge of turbulent flow.

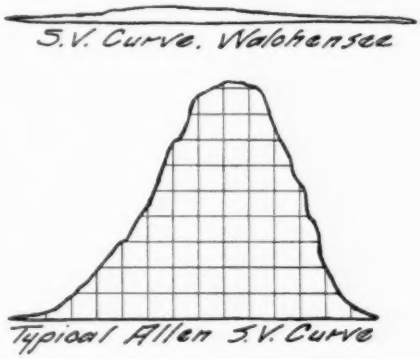
Research Institute for Hydraulic Engineering and Water Power

Discussion of Paper by Hunter Rouse, Cambridge, Mass. [Trans. A.S.M.E. (1932), HYD-54-3], Describing Large Open-Air Hydraulic Experiment Station Near Munich, Germany

C. M. ALLEN.[1] Inasmuch as the paper entitled "Research Institute for Hydraulic Engineering and Water Power," by Hunter Rouse, was published without being presented at a meeting, the author did not have the benefit of the usual criticism and comment that are a valued feature of oral discussion. Hence it is necessary to call attention to certain statements concerning the salt-velocity method of water measurement appearing in the paper that should be cleared up.

The last two paragraphs of the paper practically say that the current meter is by far the best method of water measurement. This conclusion is so contrary to the data set forth in the paper, is so contrary to American practice, and the whole matter is so important to manufacturers and engineers all over the world that it should not go unchallenged.

In the Walchensee laboratory tests the results of four different methods of water measurement were compared with those obtained by the volumetric method. The measuring basin, the water-level gages, and the test apparatus used in the volumetric measurement appear to be correct in theory and practice and no doubt they were properly installed and carefully observed during the test. The values for discharge by this method should be within a small fraction of 1 per cent of the true values.



The four methods which were compared with the volumetric are the weir, current meter, salt velocity, and salt titration. I assume that the laboratory personnel was familiar with the measurement of discharge by weir and by current meter, and in the absence of any knowledge of the matter, by salt titration.

The author briefly describes the Allen salt-velocity method as conducted at this laboratory, when as a matter of fact, basing our opinion upon the description and results as given, it appears to be a long way therefrom. The detailed description of how these tests were made is so incomplete that it is difficult to offer much helpful comment. For instance, we should like to know the size and type of injection valves, whether a-c or d-c current was used, what voltage was used, and how the height of the salt curves was intensified. More information about the electrodes would be in order and a sample salt curve would be very desirable.

Apparently the personnel of this new laboratory was attempting a few of the procedures that were tried out over ten years ago in the Alden Hydraulic Laboratory, most of which were discarded because of errors,[2] and had no knowledge of developments since 1923 and consequently did not use the accepted standard methods. It is not surprising that, as the author states, they did not know the proper location of the electrodes. That their very first test showed results within 1.2 per cent of the volumetric results speaks very well for the salt-velocity method in the hands of inexperienced men.

The author states that the purpose of these tests was to compare the leading European and American methods of measuring penstock discharge, and that "these experiments were made by recognized authorities in the field of practice." We cannot agree with this statement as it applies to the salt-velocity method.

These pipe-line tests were made prior to the laboratory tests, and, so far as we know, no one connected with them had had any practical experience with the salt-velocity method. Mr. Howland, of the British Pitometer Company, Ltd., London, made both the pitometer and salt-velocity tests. His experience with the salt-velocity method was confined to a few hours' visit to the Alden Laboratory. It was understood that he would be supplied with special instructions before a test was made. Instructions were cabled, but they were not followed. If Mr. Howland had been able to do as instructed in the one cablegram sent, he would have gotten even better results than he did. If he could have had full instructions and an opportunity to carry them out, he would have made an exceptionally accurate test, because the conditions at Walchensee were ideal for a perfect test.

FIGS. 1 AND 2 SALT-VELOCITY CURVES

In the conduct of the test only one pop valve was used for salt introduction, and that was located in the center of the pipe at the lower end of a bend where the distribution of instantaneous velocities was very bad for a pipe line. Standard practice is to install two to four pop valves at the upper end of the bend or, preferably, well downstream in a straight section of pipe. The Walchensee penstocks were about 1200 ft long and afforded ample room for an ideal test section. No advantage was taken of the total length of penstock.

Four electrode stations were used. Standard practice would have used only one. The two upper stations at Walchensee were improperly located, the electrodes were of unsuitable design, i.e., without making complete traverses, and the results were rejected for obvious reasons. These two sets of electrodes never should have been installed, but the runs in which they were used constituted more than half of those made.

The third electrode was so close to the fourth and final one that the two salt curves overlapped. A correction was made for this,

[1] Professor of Hydraulic Engineering, Worcester Polytechnic Institute, Worcester, Mass. Mem. A.S.M.E.

[2] See "The Salt-Velocity Method of Water Measurement," by C. M. Allen and Edwin A. Taylor, presented at the A.S.M.E. Annual Meeting in December, 1923, and published in MECHANICAL ENGINEERING, January, 1924, p. 13.

but the third electrode was unnecessary and should never have been installed. For research purposes duplicate sets of electrodes are sometimes installed, but they are always located far enough apart to prevent interference of the salt curves.

The results from the two lower electrode stations were computed and appear in Table 3 of the paper. Direct current was used, while only alternating current is recommended. Owing to the use of direct current, voltage regulation by resistance, long-line resistance in the electrode leads, and to the tiny electrodes used, the salt curves from the Walchensee instrument were very difficult to compute accurately. The accompanying Fig. 1 shows a sample salt curve from the Walchensee test and Fig. 2 one from a typical salt-velocity test properly conducted. The Walchensee curves could and should have been five times as high as they were. The diameters of the pipe and the lengths of the test sections which produced these two curves were about the same in each case.

In the next to the last paragraph of the paper the author discusses the "poor results" obtained at Walchensee by the salt-velocity method and the "very dependable results" by current meter. The German Research Institute makes the current meter standard for accuracy of water measurement. Obviously the author has never computed the actual percentage of variation in values for Q at Walchensee by current meter and by salt velocity.

Referring to Table 3 of the paper and assuming the current-meter results as correct, then the results by salt velocity vary from current-meter values as follows: Experiment No. 7, — 0.25 per cent; No. 8, + 1½ per cent; No. 9, + 0.033 per cent; No. 10, — 0.2 per cent. Three out of four runs show a variation of less than 0.25 per cent, and obviously something is

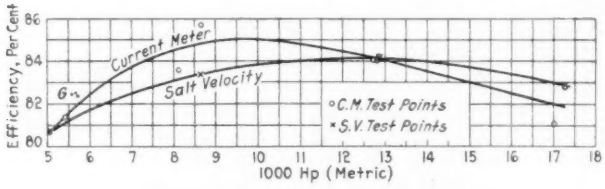


FIG. 3 WALCHENSEE TESTS, 1929

wrong with the values given for the other run, No. 8. While the values for Q by current meter and salt velocity vary by 1½ per cent, the corresponding values for efficiency vary by 2¾ per cent. This is impossible.

If the author will plot all the values for Q and efficiency against either gate opening or horsepower for the two methods, he will conclude that the salt-velocity values look more reasonable for experiment No. 8. The current-meter value for efficiency of 85.66 per cent looks wild for this run.

Fig. 3 is a curve sheet showing efficiency on horsepower plotted from Table 3 in the paper but omitting the pitometer results. It is Fig. 40 of the paper with the actual test points shown. In making up Table 3 the salt-velocity values for runs Nos. 1 to 5, inclusive, were rejected by the author because the wrong electrodes were used. Run No. 6 was rejected on account of errors in load, and runs Nos. 11 and 12 were for the Gibson method only.

Which shows greater variation, the nine current-meter points or the four salt-velocity points? The current-meter point at 8664 hp, or run No. 8, is under suspicion. If that value and one low value at full load are ignored, then the current-meter curve and the salt-velocity curve would practically coincide. So much for "poor results" by the salt-velocity method and "very dependable results" by current meter.

The author states that "the salt-velocity method showed excessive departure from its own average of readings except on the stretches from the injection point to the third and fourth electrodes." Of course, they would with the salt introduction made with one pop valve at the center of the pipe and at the lower end of a bend and with small traversing electrodes (2 in. long × 1¼ in. wide) but with no traverses made. The plant operator could not arrange for making complete traverses before the regular test.

One set of standard electrodes should have been used. The first and second electrodes should never have been installed. Electrode No. 3 was actually an injury to the test, since it was so close to No. 4 that the two salt curves overlapped. It was unnecessary for any field testing, but if installed for research purposes, then it should have been located 100 ft upstream or, better yet, located where it was and electrode No. 4 moved from 100 to 400 ft downstream. All of these things would never have occurred in a properly conducted test, and this discussion would probably have been unnecessary.

In 1930, Dr. Otto Kirschmer, head of the Research Station for Water Power and Hydraulic Design, published the results of these Walchensee tests. At that time he was at the head of this German Research Institute. The author's Table 3 is a copy of Dr. Kirschmer's table of results. The following is quoted from the original paper: "Fig. 19 shows further that the salt-velocity method does not vary very much from the meter method." Dr. Kirschmer also stated that the salt-velocity method would have given better results had the *standard type* of electrode been used. In view of both of these statements, how has the author arrived at his conclusions in regard to the salt-velocity method?

It should be emphasized that, in common with all other methods of water measurement, only those who are qualified and who have had experience with a method should use it. If others desire to use it or experiment with it, they should acquaint themselves with the latest developments and should not publish their results unless all the conditions and facts are fully described.

A. W. K. BILLINGS.[3] The tests under discussion were initiated in connection with the efficiency guarantees in a contract with a European manufacturer for an impulse wheel of 70,000 hp. maximum capacity for a plant near São Paulo, Brazil.

For many years in connection with plants in Spain, Mexico, and Brazil we have had difficulties with the various methods of specifying and of testing efficiency; these were particularly evident in comparing guarantees of European and American manufacturers. As a result of this experience and after careful study we have adopted and now insist upon the salt-velocity method of testing, and, for low-head plants, alternatively the Gibson method.

The purchaser, in continuing this policy, therefore required the German manufacturer to satisfy himself of the reliability of the method before the informal award for the unit in question would be confirmed by a written contract. The manufacturer arranged with the Research Institute to do this work, and the scope of the tests was extended by it to include the pitometer and salt-titration methods.

The Walchensee plant has an important load, and the management was naturally somewhat reluctant to shut down the units for the periods desired and to prepare the penstocks to receive the electrodes. These limitations and the natural desire of the manufacturer to expedite the comparison resulted in these first tests being made without attention being given to certain details in which changes were indicated by Professor Allen. The results, however, satisfied the water-wheel manufacturer, and

[3] Vice-President, Brazilian Traction, Light, and Power Co., Ltd., Toronto, Canada. Mem. A.S.M.E.

the formal contract was made on the basis of the salt-velocity method.

It was not expected initially that these tests would be published, and the special motive and circumstances should be borne in mind in discussing the results.

In our work we have found the current-meter method laborious under the very best conditions, even though accurate in expert hands, while in turbulent flow and with entrance conditions far from ideal, as in many commercial plants with large units, it is subject to large errors and difficult of interpretation. We have found that both the salt-velocity and Gibson methods check satisfactorily with each other, and, where possible, with volumetric measurement; and we now decline to use, for official acceptance of large units under practical conditions, others such as the current-meter, weir, or titration methods.

It is our opinion that European engineers, while conservative and reluctant to adopt these new methods, will gradually come to accept them, especially for testing large units where the weir and titration methods are impracticable and the current-meter method leads usually to controversy regarding the characteristics and accuracy of the various types of meter selected.

Edward S. Cole.[4] This paper gives an excellent description of the Walchensee Hydraulic Laboratory and of certain flow measurements made in the pipe line of a nearby power plant which it was the writer's privilege to witness; but with several of the statements and conclusions concerning the pitometer tests he must disagree.

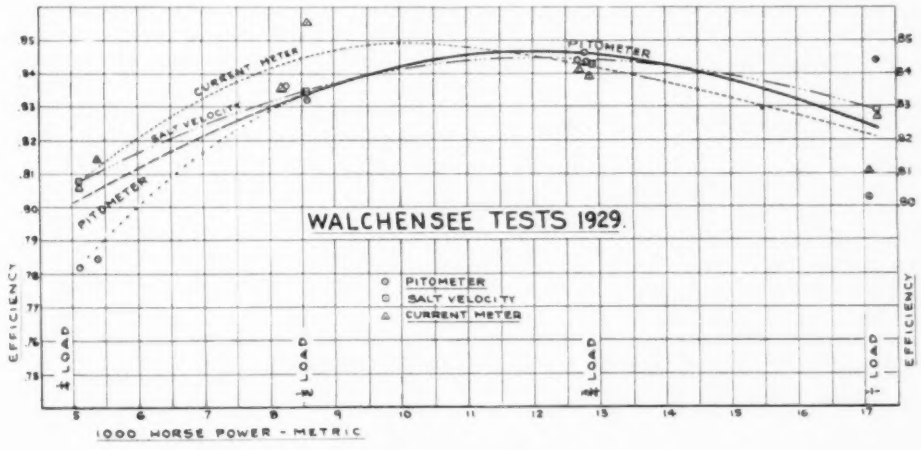

Fig. 4 Walchensee Tests, 1929

The accuracy of a pitometer gaging depends upon four things: (1) Calibration of the instrument; (2) ability to read the axial component of angular flows; (3) selection of a suitable gaging point; and (4) experienced handling by the engineer conducting the tests.

These pitometer measurements at Walchensee were unofficial but were made by The British Pitometer Co., Ltd., for its own information. The instrument had been calibrated by a well-known hydraulic laboratory with a high degree of accuracy, except at the lowest rate of flow where the laboratory now admits a probable error of 2 or 3 per cent.

The gaging point was quickly shown to be unsuitable by the first velocity traverses made, but local authorities would not permit a change. A vertical bend about 100 ft above the gaging point caused a disturbed flow, and it would have been easy to secure a longer tangent by moving it farther down the pipe line.

The author makes reference to unstable U-tube readings, but these were probably due to the gaging point with its disturbed flow. He speaks of "supporting rods" for the pitometer and current meters, but no supports are needed by the pitometer, which is introduced through a valve attached to the penstock wall. This may be done without unwatering the line if necessary.

The pitometer gives velocity readings within $^1/_4$ in. of the pipe wall, a decided advantage in computing the velocity traverse, since current meters can hardly read closer than 2 in. from the wall, involving uncertainty as to this outer 2-in. ring, which has about 12 per cent of the total pipe area and is the region of greatest velocity change.

The author makes a claim as to the relative speed of taking pitometer readings, but in the writer's opinion speed is largely a matter of organization. The pitometer responds to changes of velocity quite as quickly as the current meter.

In the original report of Dr. Kirschmer the statement is made that "Pitot measurements should give higher velocities at low flows and lower velocities at high flows than current meters." This evidently is based upon the assumption that the "pitot" has a uniform coefficient throughout its range, which is certainly not true of the pitometer.

Now as to the pitometer results (see Fig. 4):

At one-quarter load the two pitometer tests agree closely with each other, but are about 2 per cent below the salt-velocity and current-meter values. This is accounted for by the laboratory error at that rate of flow, as noted above.

At one-half load there were two pitometer tests which came within $^1/_2$ per cent of each other, agreeing closely with the one salt-velocity test and with the lower of the two current-meter values, the upper of which, by the way, seems to be about 2 per cent too high.

At three-quarters load the three pitometer tests agreed with each other and the single salt-velocity test within less than $^1/_2$ per cent. The two current-meter values were also very close, and certainly this agreement of the three different methods of measurement is most interesting.

At full load the average of the two pitometer tests agrees closely with the average of the two current-meter values and with the single salt-velocity test, but the variation in pitometer tests at full load probably was due to the disturbance of the upstream bend.

A considerable number of pitometer gagings made in waterpower penstocks of American and Canadian plants have demonstrated the extreme simplicity and high degree of accuracy of the method.

Marcus Mousson.[5] The tests at the Walchensee development are the first in history where so many practical testing procedures of European and American origin have been compared. The physical layout of the plant properties is equally favorable for all methods used, which is seldom the case at other hydroelectric developments. In spite of this the results obtained

[4] Hydraulic Engineer; President, Pitometer Co., New York, N. Y. Mem. A.S.M.E.

[5] Hydraulic Engineer, Safe Harbor Water Power Corp., Baltimore, Md.

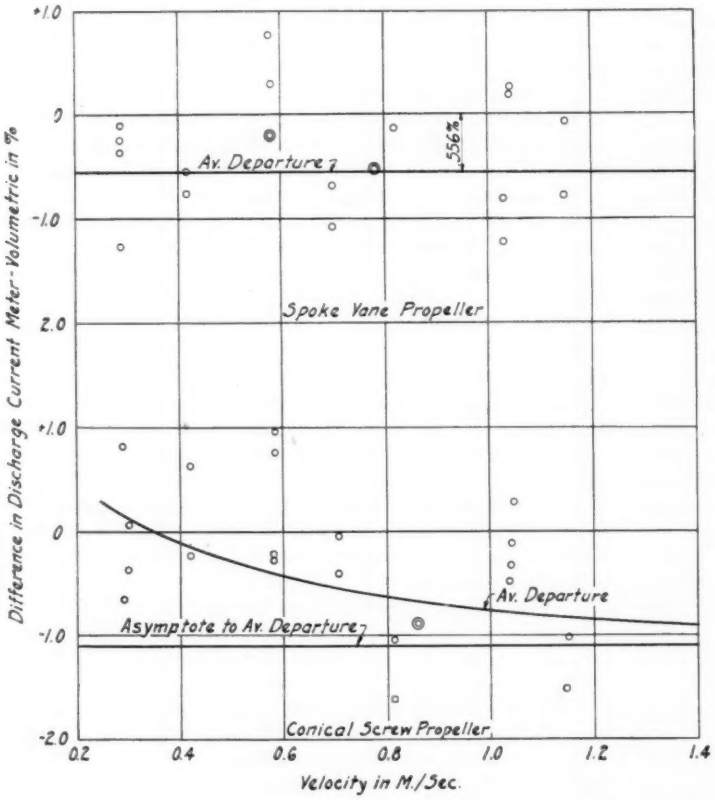

FIG. 5 AVERAGE DEPARTURE CURVES OF SPOKE-VANE AND CONICAL-SCREW METERS FOR WALCHENSEE FLUME TESTS

and the conclusions drawn therefrom need a more careful analysis to avoid being misleading.

Unfortunately, some European engineers have concluded from the results that the Allen salt-velocity, Gibson, and pitot-tube methods will be permanently abandoned in the near future. However, it must be said that in America we see no weakening of faith in these methods where conditions are suitable, but rather a development of current-meter application for conditions where satisfactory tests by means of other methods do not appear to be possible.

Because of discrepancies that have occurred in the past between various testing methods, some prejudice may have sprung up against one or another method. It has been too often specified in turbine contracts, and has frequently been standard practice, that the acceptance tests should be made by means of two methods; though the physical layout of the water passage may have not been favorable for the application of one of them.

There are enough data at hand to substantiate the fact that American and European methods give identical as well as reliable results when the layout is favorable to the same degree for the various methods. Much harm may be done to any method when the physical conditions are unsuitable or if the test personnel should lack in necessary familiarity with the methods and the difficulties which may be encountered.

It would be very desirable if all essential precautions were to be taken before actual construction of a hydroelectric development to guarantee a water passage suitable to the method by means of which the turbine acceptance tests will be made. Assumptions that hydraulic conditions will be satisfactory alone are not always justifiable, as results of model tests may show that alterations in design are desirable and essential.

Enough experience in current-meter and salt-titration procedures was at hand at the Walchensee to insure reliable results with these methods, but it is hard to believe that the experimenters had sufficient knowledge and practice with the Allen salt-velocity and Gibson methods to obtain satisfactory results, as extensive experience is essential to the successful application of these typically American methods.

Some comparative measurements have been made at the hydraulic laboratory of the Pennsylvania Water and Power Company at Holtwood. When the laboratory was put in service, the venturi meter measuring the discharge was calibrated by means of the Allen salt-velocity method. Conditions suitable to this particular method are provided by a straight penstock section of sufficient length. Before the turbine tests at Safe Harbor, two current meters were tried out in the flume of the above-mentioned laboratory and a very close check was arrived at between discharges measured by the venturi meter, calibrated by the Allen method and the current meters. The average discrepancy established was less than 0.10 per cent.

A careful analysis of the current-meter measurements presented in the paper produces some valuable new data and permits fundamental conclusions to be drawn regarding the application of current meters.

In Fig. 5 are plotted departures of discharges measured by means of current meters from volumetrically determined quantities in per cent versus mean velocities at the current-meter measuring section for the flume tests (runs 1 to 28, inclusive). It is apparent that the spreading of the test points is quite large and that the distribution is not alike for both meters

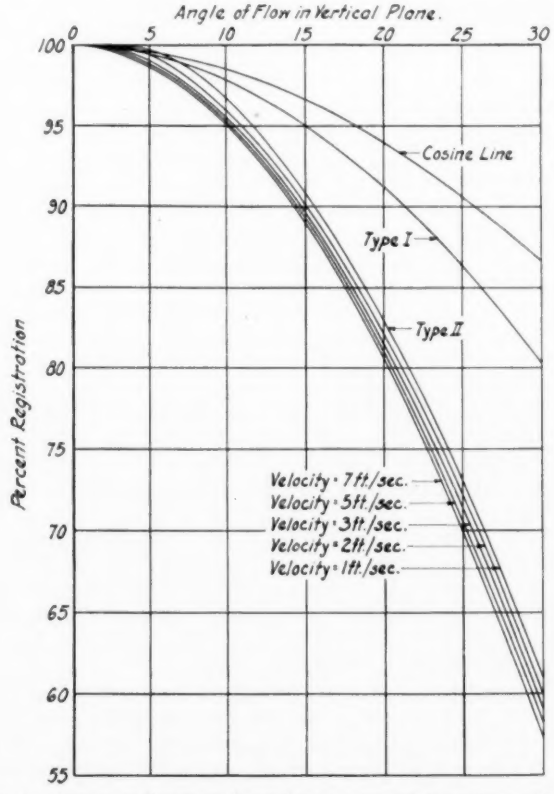

FIG. 6 AVERAGE OBLIQUE-FLOW CHARACTERISTICS OF SPOKE-VANE AND CONICAL-SCREW PROPELLERS USED AT SAFE HARBOR

There is a noticeable and actual trend toward minus values for the conical type with increasing velocities. Hereafter, the spoke-vane and conical-screw propellers will be referred to as Type I and II, respectively.

A detailed investigation has been made on the behavior under oblique-flow conditions of Type I and Type II propellers of Ott manufacture in connection with the calibration of the current meters for the Safe Harbor turbine field tests.

From Fig. 6 one may realize that there is a fundamental difference between the oblique-flow characteristics of the two propeller types aside from the magnitude of underregistration. The greater the velocity the more Type II underregisters for a given obliquity. On the other hand, for Type I they are not affected by velocity changes.

Based on the above and the following reasons, it is safe to state that both meters used at the Walchensee flume tests indicate oblique flow at the measuring section, independently of one another. The increase in underregistration of Type II with increasing velocity could only have been caused by angular flow. On the other hand, Type I indicates also obliquity, as only four test points show overregistration (tests 12 and 25). If the flow had been laminar, a more equal distribution between plus and minus departures would have been obtained for the Type I propeller.

It is not believed that turbulence was responsible for the results shown in Fig. 5, as it would have affected both current meters more and more with increasing velocity. The average departure curve for the Type I propeller is parallel to the horizontal axis of the coordinate system, and the same curve for the Type II is approaching an asymptote also parallel thereto, located for this particular case in the vicinity of approximately minus 1 per cent, or about twice that for Type I.

Fig. 7 shows the oblique-flow characteristics of Type I and Type

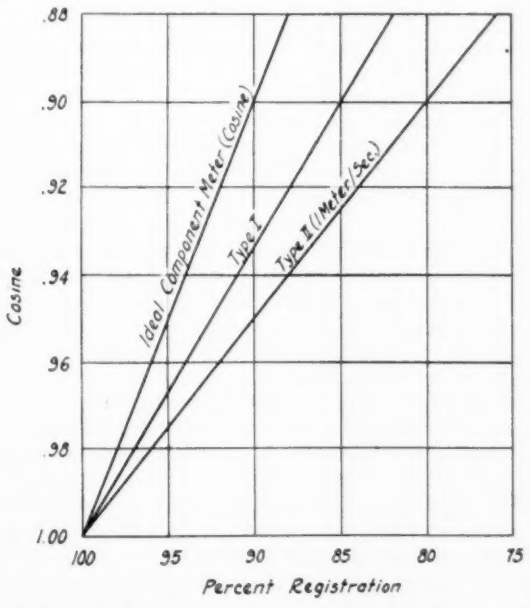

FIG. 7 OBLIQUE-FLOW CHARACTERISTICS OF SPOKE-VANE AND CONICAL-SCREW PROPELLERS USED AT THE WALCHENSEE, MOUNTED ON CURRENT-METER BODY TYPE V "TEXAS"

II propellers used at the Walchensee for a velocity of 1 meter per second. It may be noted that the Type II propellers tend to overregister slightly at small obliquity and very low velocities (see Fig. 6). The results as obtained at the Walchensee are quite logical and speak well for the precision with which the current-meter work has been done; although it has to be stated that for practical use the Type I propeller is more reliable, as the velocity range in general will be well above the one chosen for the Walchensee tests.

The experimenters averaged the departures of the two meters without paying any attention to the oblique-flow characteristics. In view of this fact European engineers have been puzzled by the

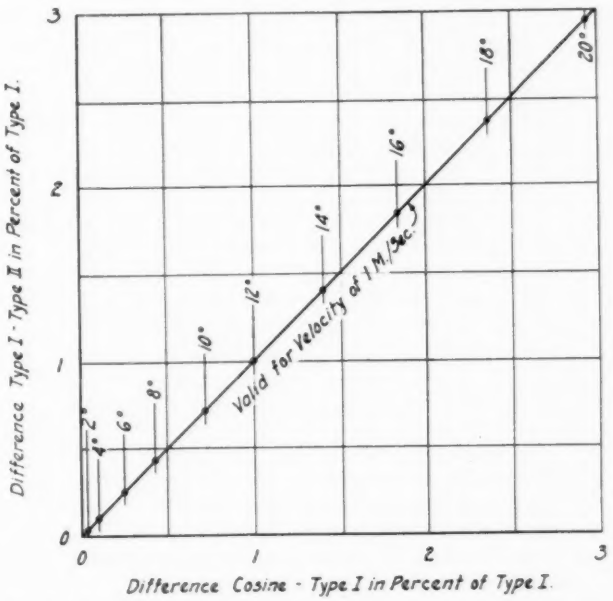

FIG. 8 CORRECTION CURVE FOR MEAN VELOCITIES, FOR MEASUREMENTS MADE WITH THE CURRENT METERS USED AT THE WALCHENSEE

result as presented, as it has been shown in the past that the Type I propellers of Ott manufacture have an oblique-flow characteristic closer to the cosine line than the Type II, and therefore the Type I propellers have been used more or less exclusively for turbine acceptance tests. It was suspected that algae or grass were caught in the spokes during the tests at Walchensee and that their presence slowed up the Type I propellers sufficiently during various runs to produce the established average deficiency for this type.

In connection with these tests it has been stated by Dr. Kirschmer and Mr. Esterer (*Z.V.D.I.*, Vol. 74, p. 1504) that none of the methods used at the Walchensee showed any dependence upon changes in velocity. That this statement does not hold true for the Type II current meter has been demonstrated by the ratings at the Bureau of Standards shown in Fig. 6, as well as by the average departure curve for the same type in Fig. 5.

To substantiate further these conclusions, a correction curve for mean velocities, discharges, or turbine efficiency is given in Fig. 8. The curve is derived from the original oblique-flow characteristics of the two meters used at the Walchensee put at our disposal by Dr. Ott, manufacturer of the meters, and presented in Fig. 7. This curve is true for velocities in the vicinity of 1 meter per second and will differ very slightly from the correction curves for higher velocities. As the underregistration of the Type II propeller is twice that for the Type I, the curve is a straight line, inclined at 45 deg, when the scales for the two axes of the coordinate system are chosen identical.

Special attention should be given the fact that the curves given on Fig. 7 are straight lines, because it is of fundamental importance. This characteristic may have been overlooked, because angle of flow has usually been plotted versus per cent registration.

Let it be assumed that there is a certain constant discharge at a gaging section. Then the mean ordinate vertical to the plane of measurement will be of constant magnitude.

When current meters with a straight-line oblique-flow characteristic, such as those in question, are used, we shall, theoretically, obtain at all times a discharge of the same magnitude; though the measured discharge will deviate from the true discharge a definite amount, depending upon the oblique-flow characteristic of the meter type used for the measurements. That the difference theoretically would be constant is due to the straight-line relation between cosine and per cent registration.

The correction curve shown in Fig. 8 will also be a straight line due to the individual linear oblique-flow characteristics of each propeller type. Therefore it is not necessary to correct for the velocity components registered in each current-meter location, but we may make use of the correction curves in reference to the established mean velocities or discharges obtained with each type of meter.

It is advisable to establish separate discharge curves obtained by means of each type of meter before the correction is applied, in order to eliminate the test-point spreading and because it is not essential that the true discharges for Types I and II current meters be alike, as the measurements do not have to be made simultaneously.

In connection with turbine testing, another procedure may be adopted—that is, to establish first the efficiency curves based on the discharges measured by means of each type of meter; the true efficiency may then be determined by means of the correction curves. A procedure of this kind is permissible, as efficiency is proportional to discharge.

It is apparent that an average correction of 0.5 per cent for the Type I measurements is necessary, as the vertical distance between asymptote for the Type II departure curve and the average underregistration for the spoke-vane current meter are of the same magnitude. (Correction was made by means of asymptote, as the oblique-flow characteristics of Type II for 1 m per sec only is known.) The results obtained by the Type I propeller justify this assumption, because a correction of 0.5 per cent would almost give a complete check with the volumetric measuring method, as the average underregistration would be 0.05 per cent, a result of utmost precision.

Based on the foregoing it may be realized that the two-type current-meter method is essential for results of high accuracy, even for the most ideal approach conditions. Results obtained with a water passage less favorable than the one at hand for these tests may be seriously doubted regarding their precision if the measurements have been made with but a single current-meter type. It has to be borne in mind that for gaging sections generally available for turbine acceptance tests the approach conditions are quite different, and most probably the mean angularities will be in excess of the one established for this particular set-up.

From the correction curve given in Fig. 8 it may be seen that the average angularity was approximately 9 deg. A value of this magnitude is astonishing for the ideal approach provided; although this result still further strengthens the present-day theory that laminar flow does not exist in open flumes and penstocks, but that the individual water particles follow an irregular path deviating by a large amount from the direction of the flume axis horizontally as well as vertically. This phenomenon is the very reason for the success of the salt-velocity method, and its existence has been demonstrated in connection with that method.

As in general approach conditions at low- and medium-head plants are not as ideal as those which were available for the flume-gaging section of the Research Institute, it had been adopted as standard practice abroad to provide temporary roofs or intake pier extensions in order to straighten out the flow to a satisfactory degree. However, based on the conclusions arrived at above, it may be safe to state that the magnitude of corrections due to obliquity may exceed 1 per cent even when special provisions have been made. This explains to a certain extent the high turbine efficiencies reached abroad.

It is to be regretted that the conical-screw meter alone was used for the penstock tests at Walchensee, as valuable data could have been obtained regarding the magnitude of obliquity to be expected in penstocks. It may be safe to assume that the mean angularity for straight penstock sections will be of the same magnitude as the one established for the flume at the Walchensee.

It has been pointed out above that the spreading of the test points is considerable for the flume tests. The magnitude of the spread is about 2.3 per cent for the spoke-wheel propeller (disregarding test 18-B) and about 2.6 per cent for the conical-screw meter. Most probably individual differences of smaller magnitude would have been obtained if no water had been wasted at the downstream end of the set-up, because the volumetric basin could not hold the total discharge passing the current-meter section during the time necessary for the measurements.

This difficulty could have been easily overcome in using more than one current meter of each type. It is believed that more consistent results would have been obtained in using five meters simultaneously mounted on a supporting rack. Arrangements of this type have been adopted as standard practice for turbine testing. By means of such a set-up the time interval necessary for the measurements would have been only 15 per cent of the one used for the tests and, furthermore, no water would have had to be wasted because the total discharge for one test run could have been retained in the basin.

Well-organized current-meter measurements may be made with a smaller spreading of test points, which is essential for this particular measuring method on account of the considerable time necessary to compile the data, and, in addition, because only a minimum of test runs is permissible from an economic point of view.

It is general practice abroad to sketch in the velocity diagrams close to the wall without actual measurements by means of pitot tubes. It is not necessary to adopt for this a pitot tube of the differential type, as one is not interested in absolute velocity values but in the shape of the velocity curve. When a supporting rack is available, pitot tubes, provided with one impact opening, may easily be located between the first meter and the wall, as well as between the first and second current meters. The shape of the velocity diagram derived from the pitot-tube measurements will then be tied in with the absolute velocity values obtained by the current meters. When such an arrangement is used, enough overlap is assured to make this tie-in possible. The pitot-tube tests can be made either simultaneously with the current-meter ones or separately for various discharges at the gaging section. A similar procedure is desirable for the bottom of an open flume, as was available for these tests or for power-house intakes. The total area of the gaging section at the Walchensee flume tests was relatively small and the area affected by wall and bottom is an appreciable percentage of the total area of water passage. Pitot-tube tests of the kind outlined above may have been of some assistance and may have affected the precision of the individual test points to a certain extent.

What has been outlined above is also important for the penstock measurements. The layout of the latter tests in reference to the current-meter setting cannot be called satisfactory. Only two diagonals intersecting at right angles were explored with the current meters, and therefore approximately 40 per cent of the penstock cross-section was not investigated. Too much leeway is left with such an arrangement. It would have been more desirable to install a revolving current-meter supporting rod

pivoted at the penstock center with enough current meters to cover the total diameter simultaneously.

One may conclude that too much weight was given to the distribution of the test points as shown on Fig. 5 and might call the distribution merely accidental. Fig. 9 gives the theoretical average departures from the true discharge for a wide velocity range to be obtained with the Type I and II propeller meters used at Safe Harbor for various mean angularities. The departure curves are based on the calibrations made at the Bureau of Standards. The plotting thus obtained is identical with the actual results at the Walchensee (see Fig. 5) and speaks well

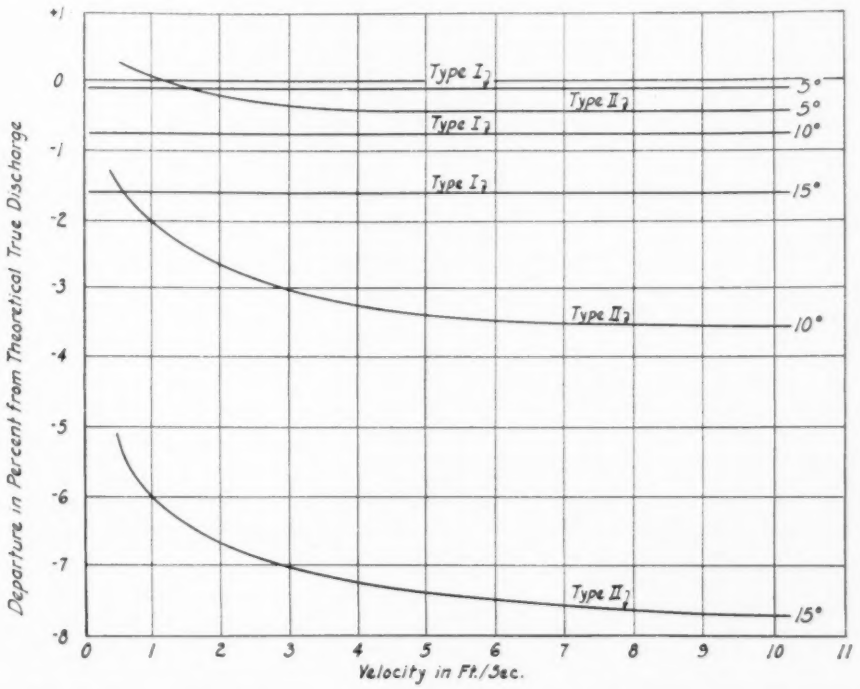

FIG. 9 THEORETICAL DEPARTURE CURVES FOR VARIOUS MEAN ANGULARITIES OF OTT CURRENT METERS USED AT SAFE HARBOR

for the precision with which the current-meter work has been done. The slight difference in shape of the Type II propeller departure curves is due to the fact that the oblique-flow characteristics of the Type II propellers used at the Walchensee and Safe Harbor are different, because the nominal pitches of the meters were 25 cm and 50 cm, respectively.

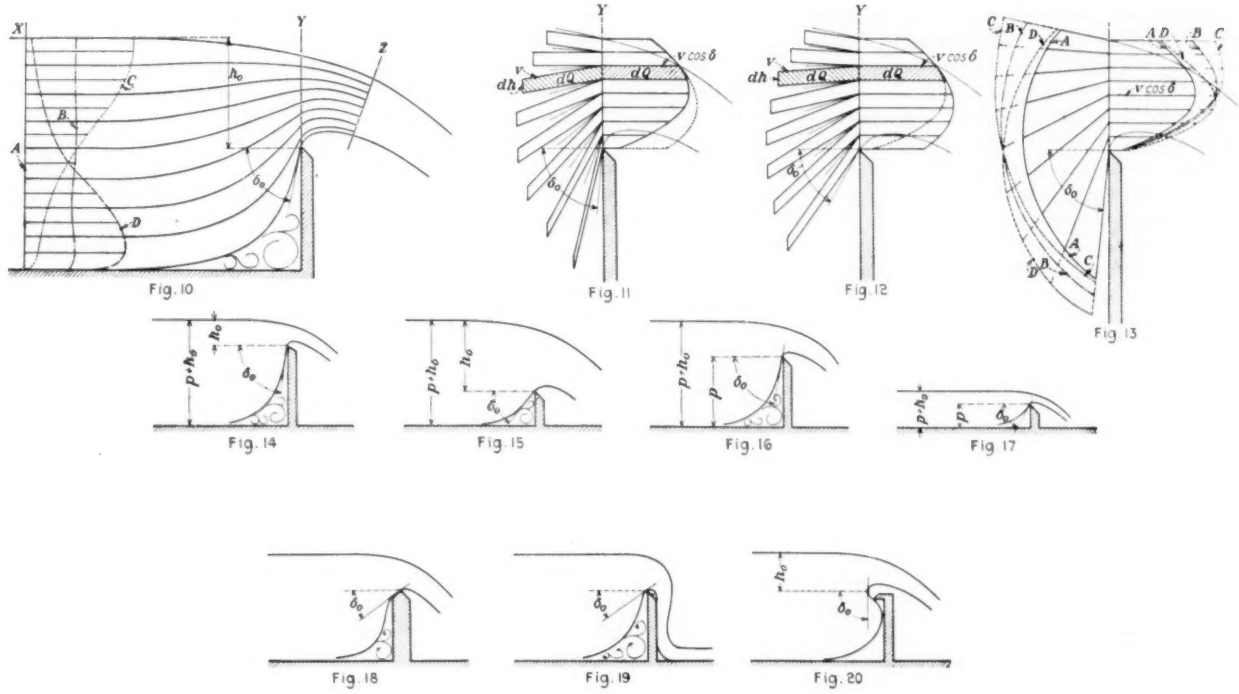
It has been pointed out by Dr. Kirschmer (*Z.V.D.I.*, Vol. 74, No. 7) that the established average current-meter departures of —0.3 and —0.6 per cent do not justify any doubt regarding the reliability of the current-meter method, because the magnitude of this deficiency is within the range of calibration discrepancies obtained at various rating stations.

Based on the analysis presented in the present discussion, this statement is not valid but needs some clarification. There are quite a number of calibration stations in existence, but it is believed that the most reliable ratings are made by Dr. Ott in Kempten, Germany, and by the Bureau of Standards in Washington, D. C. For velocity ranges generally available at current-meter gaging sections in connection with acceptance tests, these two stations check one another within 0.1 per cent. The main reason for this close agreement is that especial precautions have been taken at low-rating car speeds. All other rating stations have some pecularities which seem to make them unsuitable for current-meter calibrations in connection with turbine acceptance tests. The coinciding of the ratings obtained by Ott and the Bureau is very desirable, as efficiencies are measured by means of an identical scale, both here and abroad.

It has often been advocated to calibrate current meters in flowing water, and such a scheme has been mentioned in connection with the National Hydraulic Laboratory. Some engineers in this country have even seriously doubted the justification of current-meter measurements as long as this rating procedure was not adopted. However, based on the foregoing analysis, it may be realized that when two types of current meters are used, rated in still water for straightforward and oblique flow, true discharge measurements will be obtained.

The small discrepancy mentioned previously between the salt-velocity and current-meter methods established at the Holtwood Laboratory is based on the two-type current-meter method. Two series of runs were made, with different approach conditions for each series. The differences obtained between the two methods in both series of test runs were alike, namely, —0.08 per cent, taking salt velocity as standard. The conventional average differences, that is, the differences for each propeller type alone for both series of runs, were —0.35 per cent and —1.01 per cent for Type I and Type II, respectively.

It is hoped that the material here presented will be helpful in showing that the two-type-propeller current-meter method is essential, as turbine efficiencies obtained with one type, for instance, the spoke-vane type, are too high, even when all precautions have been taken to straighten out the flow by means of temporary roofs or intake pier extensions, and even in the case when the measurements are made in penstocks.



Another major advantage of the two-type current-meter method is that temporary installations may be omitted, as the influence due to oblique flow can be estimated. Such a procedure saves considerable expenditures and permits making the acceptance tests under actual operating conditions.

A. OTT.[6] It may be regarded as an open question whether or not too much is expected of the gaging method by means of a "standard weir," keeping in mind the various factors influencing the discharge. Based on tests in a small glass flume, the standard weir formula may be reconstructed so that the effect of the individual influences are expressed within the formula itself.

Fig. 10 illustrates the flow over a sharp-crested weir without side contraction. At section *X*, located a certain distance upstream from the weir, the water filaments are moving nearly parallel, although a different velocity is prevailing in the various flow layers. The vertical velocity diagram corresponding to this assumed flow condition will have, in general, a shape corresponding to one of the typical cases, *B*, *C*, and *D*, shown in Fig. 10.

In approaching the weir the flow filaments are gradually concentrated more and more until the maximum angular convergence is reached at the nappe section *Y*. Variable eddies are in existence between the lowest filament of flow and the physical

[6] A. Ott Math. Mech. Institut, Kempten, Germany.

FIGS. 10–20

boundary—that is, the bottom and the upstream side of the weir. Small, thin flow filaments, that is, horizontal whirls, are separated from the eddies and rise along the upstream side of the weir. These rising horizontal whirls naturally influence the lowest layer of the nappe at the crest of the weir, causing a change in the direction of the lowest flow layer, which will be deflected to an angle in reference to the upstream face of the weir.

The angular convergence decreases rapidly as soon as the nappe has left the crest and at section Z the flow filaments are again more or less parallel. Formerly section Z was usually taken as a base for the theoretical investigations to establish the discharge formula of weirs. Therefore a water quantity was estimated by multiplying the area of cross-section of the nappe by the velocity existing at this section. One assumes that the thickness of the nappe at this section bears a certain definite relation to the more easily measured water depth above the crest h_0, in order to avoid the difficult measuring of the nappe thickness at section Z. This definite relation mentioned above is represented by the coefficient of contraction.

It is believed that section Y would furnish better information of the discharge conditions, as the various elements of flow may be studied easier at that location.[7] This will be substantiated by the following simple illustrations:

In Figs. 11 and 12 are shown the discharge quantities for two flow conditions over the weir. The quantities are represented by the respective areas. Depth and velocity are taken alike for both cases, although it is assumed that the individual flow filaments have a different slope. To the left of section Y are plotted the partial quantities dQ, represented by small parallelograms lying in the direction of flow. Their long side may correspond to the velocity v, whereas their small side, being parallel to section Y, may represent the element of height dh; whence their volume becomes $dQ = v \times \cos \delta \times dh$.

To the right of section Y the same strips of area are changed into parallelograms of rectangular shape. Their height is dh and their length is equal to $v \times \cos \delta$. The sum of all the rectangles is equal to the discharge when the smooth curve is taken as the boundary for the area representing discharge quantity, and not the staggered line:

$$Q = \int v \cos \delta \times dh$$

Comparing Figs. 11 and 12 it will be seen that the quantity of discharge increases with increase of deflection of the lowest filament of flow away from the crest (that is, for smaller values δ_0). As the deflection is caused by the whirls rising along the upstream wall of the weir, and the whirls in turn become larger with increased roughness of the wall and increased viscosity of the fluid, one arrives at the conclusion that the discharge quantity will increase with increasing wall roughness and increasing fluid viscosity.

In Fig. 13 are shown four areas, A, B, C, and D, each corresponding to a discharge taking place under different conditions for the velocity of approach. The direction of flow is assumed to be identical for all four cases.

Referring to Fig. 10 the area A corresponds to discharge without any velocity of approach, and B refers to a case with an even distribution for the velocity of approach; areas C and D correspond to discharge conditions where there is velocity of approach in excess of the average near the top and bottom, respectively.

It is easy to visualize that the magnitude of increase in discharge depends very much upon the characteristic of the velocity of approach. Bottom flow increases the discharge the least, top flow the most, and the influence due to evenly distributed flow of approach lies between.

In establishing a discharge coefficient C for weir of given shape and in assuming this discharge coefficient to be the product of two factors, that is, the coefficient of convergence C_c and the coefficient of velocity C_v, one may reach the following conclusions based upon what has been mentioned above and by taking into consideration a few more graphical illustrations.

[7] Detailed analysis given in "Ausfluss, Durchfluss und Ueberfall," by Dr. A. Ott, *Wasserkraft und Wasserwirtschaft*, vol. 27 (1932), no. 18, and vol. 28 (1933). Special reprints obtainable from the author.

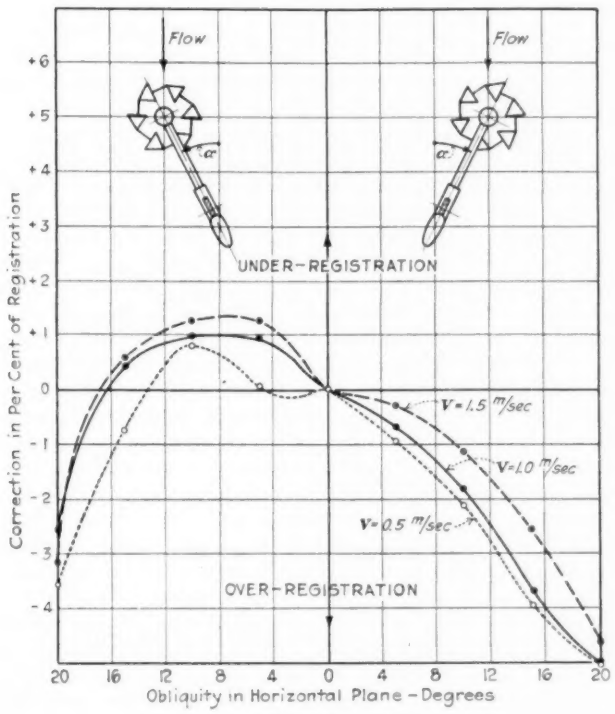


FIG. 21

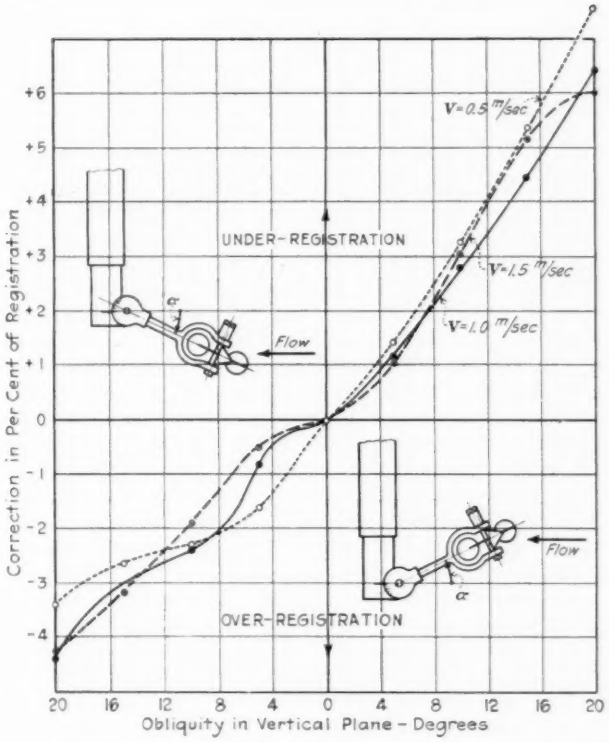

FIG. 22

C_e will be increased by any of the following factors: increase in the ratio $h_0/(p + h_0)$ (Figs. 14 and 15); decrease in the weir height p (Figs. 16 and 17); rounding off the crest (Fig. 18); suppressed nappe caused by insufficient ventilation (Fig. 19); increase in roughness of the weir surface or increase in viscosity of the fluid causing enlargement of the whirls (Figs. 10–12).

C_v will be increased by variation in velocity of approach distribution, being influenced the least by excessive bottom flow (curve *D*, Fig. 13), more by a uniform distribution (curve *B*), and the most by excessive top flow (curve *C*), and by insufficient ventilation causing a depressed nappe (Fig. 19).

C_v will be decreased by increasing angular convergence of the flow filaments, therefore slowing down their velocity.

Considering all these points, the number of which could be still enlarged as there are other influences crosswise to the direction of flow not mentioned above, it is not to be wondered at that discrepancies have been found in various discharge measurements made with weirs.

Referring to the comparative current-meter measurements, it is to be regretted that the experiments were conducted with the large Price meter, type No. 600, which is hardly used any longer; although some advantage may be derived therefrom. As this type of meter was used, the results obtained by the Research Institute may be compared with data published by B. F. Groat in 1913.[8] Mr. Groat made an intensive comparative study between a Price meter, type No. 600, and a Haskell screw-type meter. The Haskell meter had a characteristic somewhat similar to the Ott meter "Texas" equipped with a conical screw propeller and used by the Research Institute. In using both types of meter, that is, the Haskell and Price, under identical conditions, Mr. Groat found that measuring discrepancies of 1:6 are found respectively for the two types, and that therefore the result obtained by the Haskell meter should be increased by $^1/_7$ of the difference between the results of both meters.

[8] B. F. Groat, "Characteristics of Cup and Screw Current Meters," Trans. A.S.C.E., vol. 76 (1913), pp. 819–870.

Applying this conclusion to the results of the Research Institute, it is found that: Error of cup meter = +1.845 per cent; error of screw meter = —0.302 per cent; difference between both meter types = 2.147 per cent; one-seventh of this value is equal to 0.307 per cent; therefore the error of the screw meter after correction = —0.302 + 0.307 = +0.005 per cent. Mr. Groat's conclusion has been substantiated by the experiments of the Research Institute.

It is believed that one of the main reasons for the overregistering of the cup meter is that the cup wheel does not correctly integrate pulsations in flow because of the flywheel effect of the cup wheel, as well as because of the different action of front and rear side of the individual cups. Therefore somewhat larger velocity values are always established, which correspond to the average for the energy of flow. For flow without pulsation and obliquity, identical results may most probably be obtained with cup and screw meters, assuming that the mounting of the meter and its calibration are carried out in the same fashion.

The writer made some experiments with the new improved Gurley-Price meter, No. 622, and arrived at conclusions in regard to its behavior somewhat different from those generally accepted. The cup meter does not always register more than the true cosine component in oblique flow. It may over- or underregister for oblique flow from the left or the right, and from above or below, respectively.

Fig. 21 shows the corrections to be made on the measurements under angular-flow conditions and velocities of 0.5 m per sec, 1.0 m per sec, and 1.5 m per sec, in order to obtain the true velocity component vertical to the plane of measurement. It will be seen that the corrections are negative for angular departures to the right, but are mostly positive for those to the left; and further, that the meter is very sensitive for variations in flow.

In Fig. 22 are given the correction curves corresponding to oblique flow in the vertical plane. For this type of obliquity the differences are still more pronounced. For an obliquity of

10 deg to the horizontal and a velocity of 0.5 m per sec, this current meter over- or underregisters 3 per cent and 2.5 per cent for angular flow from below and above, respectively. The corrections may be estimated in accordance with a previous description given by the writer.[9]

CHARLES H. PIERCE.[10] It is not surprising that the outcome of the tests on the weir measurements "seems to substantiate the doubt that exists with regard to the use of the sharp-crested weir formulas for large discharges," as stated by the author. In fact, the several weir formulas that were used for comparison with the results obtained by the Research Institute differ as widely among themselves as they do from the volumetric results by the Research Institute for the range of head covered by the experiments.

It is now considered good practice to test the accuracy of weir measurements by means of the current meter. The use of the small Price current meter has enabled engineers of the United States Geological Survey to detect errors in weir computations, investigations generally showing that the errors were due to the use of weir formulas that were not applicable to the weirs actually used in measuring flowing water.

The relative accuracy of current-meter measurements as compared with computations of discharge by weir formulas is well illustrated by the results obtained by the Research Institute, the measurements by the two types of Ott meters being far more accurate than the results obtained by the weir formulas.

Although the author shows that the average percentage departures from the discharge as determined by the basin measurements for the 28 experiments was —0.302 for the Ott screw-propeller meter and —0.556 for the Ott vane-propeller meter as compared with +0.062 for the titration method, yet the consistency of the results of the meter measurements indicates clearly that very good work is done by the meters and that when carefully rated and properly used they can be depended upon for measurements of discharge with a high degree of accuracy.

It is unfortunate that the current meters used in the experiments by the Research Institute were limited to one type, with the exception of one antiquated large Price meter, 27 years old.

The large Price current meter was first designed and constructed by W. G. Price in 1882 and was used by him in measuring the flow of the silt-laden Ohio River at Paducah, Kentucky. The conditions under which Mr. Price was working required a meter that would function with a fair degree of accuracy at depths of 100 ft or more in water carrying as much as 5 per cent of silt and sand. The meter was not designed for use in measuring the discharge of small streams with a high degree of precision. About 30 years ago the design was modified so as to provide for the use of a smaller bucket wheel with cups of a different shape and a higher speed of rotation, although the fundamental features of vertical shaft, differential-action cups, conical pivot point, and silt-protected bearings were retained. During recent years various minor changes have been made in the construction, such as the provision for electric contact at every revolution or at every fifth revolution without changing the contact chamber, the use of stainless steel for shaft and penta gear, a pivot of larger diameter ground to a 90-deg angle cone, and specially heat-treated and tested metal for the pivot and bearing seat. It is now possible to assemble Price meters for use in low-velocity measurements which can be calibrated down to a velocity of about 0.05 fps and which show a continuous spin of $5^1/_2$ min in air before rotation of the cups is stopped by frictional resistance.

As the author has pointed out, the accuracy of current meters depends upon the ratings of the meters prior to use, with possibly a check rating after use, because only with careful and dependable ratings can meters be expected to give reliable results.

In general, the possibility of errors in current-meter ratings, as measured by percentage departures of individual observations from the mean curve, may be expected to increase as the velocity decreases. This is particularly noticeable for low velocities and is characteristic of the ratings or calibrations of all instruments where the rotating speed is the variable that is being calibrated, and it is equally true for current meters of the cup or screw type and for rotations about vertical or horizontal axes. As the frictional resistance of the moving parts of the instrument is decreased through improvement in design, better workmanship, superior metals, or other factors, the range of velocities in which frictional resistance may cause uncertainties in the rating is correspondingly reduced.

In the small Price meters as now assembled and used by the United States Geological Survey in stream gaging, the frictional resistance of the moving parts has been so greatly reduced that it appears to have no appreciable effect on the accuracy of ratings for velocities above about 0.8 fps, and in small Price meters specially adjusted for measurements of lower velocity its effect is still further reduced.

W. J. RHEINGANS.[11] The tests made to compare the various methods of measuring water which the author describes are of interest only as applied to open flumes and under ideal conditions of straight, undisturbed flow. It is to be noted that rain, high winds, and ice made testing impossible. Also that ground-water seepage was measured, although unfortunately no data are given as to the amount thereof.

In general, it is not surprising to note the apparently poor results of the Allen method as compared with the Ott meter, since the Europeans have for years been partial to the Ott current meter.

The results given substantiate the writer's contention and experience that large weirs in connection with high heads such as are used at power plants are either not very accurate or need special weir coefficients and formulas.

The metering section was ideal, having a long, straight channel, undisturbed flow, and no unnatural flow such as is found at turbine-plant intakes. But even under these conditions the Price meter read 2 per cent high, which is a strong argument against using it. What would it read under flow conditions found around power plants? The excuse that the meter was 27 years old does not mean much provided it was in good working condition and properly rated. However, since long straight channels of this sort are seldom found for a turbine test, the test made is only of passing interest.

In open-flume testing, elevation of water surface for determining areas becomes important, and no doubt wave action etc. can lead to large errors when the salt-velocity method is used.

Determination of the center of gravity of the salt curve is the main feature in the salt-velocity computations, and the method used, which consisted of burning the current intensity into paper with a spark gap, is not believed to be very accurate. A spark has a tendency to move back and forth, never going twice to exactly the same spot, and does not give a well-defined curve. Further, the personnel were apparently not familiar with the latest developments in the salt-velocity method, and therefore did not handle the tests or apparatus properly. For instance, the large minus error obtained in going from the pop valve to any of stations indicates an error in the timing of the salt intro-

[9] Trans. A.S.C.E., vol. 95 (1931), p. 829, Equation [8].

[10] Senior Hydraulic Engineer, U. S. Geological Survey.

[11] Test Engineer, Allis-Chalmers Manufacturing Company, Hydraulic Department, Milwaukee, Wis.

duction due either to water hammer or incorrect methods.

From tests at Davis Bridge, Mt. Shasta, and Big Creek, the writer has gathered enough data to convince himself that the error from pop valve to either of two electrodes or from electrode to electrode does not vary more than $^1/_2$ of 1 per cent and certainly not 4 or 5 per cent, as shown by the tests in Germany.

Either the open flume or lack of salt-velocity test knowledge is responsible for the large errors they found at Obernach, and the writer would hesitate to place much reliance on the results there with this method. Later, with tests in penstocks much better results were obtained in comparison with the other methods used.

In the salt-titration tests conditions were again ideal for accurate results. There was a good mixing, which is obtained at all power plants. However, there was exceptionally smooth flow at the sampling station, which is seldom the case at a power plant. Therefore the results can hardly be used for indicating possible power-plant results due to the highly disturbed and fluctuating flow usually encountered in the tailrace.

Individual tests made showed variations of 1 to 2 per cent, although the average for all the tests happened to be small. However, this means that five or six tests would have to be made at each gate to obtain any sort of accuracy.

The lack of knowledge of the fundamentals of the salt-velocity method by the Walchensee personnel is shown by the method of using the electrodes. Four short (2-in.-long) electrodes on the outer diameter of a 6-ft penstock will not give accurate results. Further, the velocity measurements by current meter and pitot tube were made only on one diameter, which would hardly give good results.

The disadvantage of the length of time required to make a pitot-tube traverse is pointed out, as well as the bothersome U-tube fluctuations. This is where the photoflow method could be used to advantage; it requires considerably less time than the current meter, and would probably offer less obstruction to the flow.

At Walchensee the current meter gave 1 per cent less discharge than the salt-velocity method, while at Obernach the salt-velocity gave from 1 to 5 per cent less discharge than the Ott meter. Note the close agreement between the pitot-tube and the salt-velocity methods. The pitot tube gives high discharges evidently at low flows, which fits in with Mr. Proebstel's statement that the lower the velocity, the lower the pitot-tube coefficient. Since the current meter gave 1 per cent better efficiency than the other methods, it would naturally be considered the best method.

The pitot-tube coefficient used is not given in the paper, neither the method of measuring static head etc., so we cannot draw any conclusions from these tests except that in general the methods agreed fairly closely. It is unfortunate that the Gibson method was used for only one point on the curve.

The writer agrees with the author's conclusion that performance of instruments under actual flow conditions is needed. The tests at Obernach so far have not fulfilled that need.

E. B. Strowger.[12] Reference has been made in the paper to tests using the Gibson method on one of the Walchensee units which resulted in only two usable diagrams. These two runs showed fair agreement with the current-meter results when compared with the current-meter rating curve, even though they involved a low turbine gate setting and consequently relatively low penstock velocities and probably relatively low velocities for the current meters. It was of course unfortunate that an incorrect spring adjustment in the apparatus precluded the use of the remaining Gibson diagrams.

[12] Assistant Hydraulic Engineer, Buffalo, Niagara, and Eastern Power Corp., Buffalo, N. Y.

The European designs of the Gibson apparatus have been ingeniously conceived and from appearances have been made with a high degree of precision. The results obtained at the Brunnenmühle plant by J. M. Voith using the Voith-Brecht apparatus and those obtained by the use of the Thoma apparatus (designed by Volkhardt and Deckel) were in close agreement with the corresponding weir and current meter results, respectively, taken under great care.[13] It is reassuring to one who has had the opportunity to apply the Gibson method of water measurement to a great many water-power plants to know of independent investigations of the method which show such good results.

It is the usual American practice in testing a turbine to make several runs at each gate setting, resulting essentially in a rating curve determined by averaged points. In this way accidental errors tend to be compensated. A casual or random error does not introduce a dangerous error in an average deduced from a series of readings. Accidental or casual errors of observation, as a practical matter, cancel out.

During the past summer the writer has made a series of experiments for the purpose of investigating the effect of variation in shape of the pressure-time diagrams obtained by the Gibson apparatus. These experiments were made by comparison of water measurements by the Gibson method with volumetric tank measurements using a quantity of water of about 4 cfs. As the effects to be considered were of relatively small proportions, it was necessary to reduce the probable error of the volumetric measurements by using a tank of unusual dimensions, namely, 57 ft long, 18 ft wide, and 4 ft deep. The time for filling with the quantity of water being measured ran from 10 to 15 min. The average variation between the volumetric and the Gibson measurements in one series of 15 runs was —0.2 per cent and in another series of 9 runs +0.4 per cent.

In May, 1931, the writer made an independent Gibson test of a power plant in New York State which had previously been tested by the Allen method in October, 1929. The station contained two Francis-type turbines operating under a head of about 200 ft. The results obtained by the two methods were practically identical.

In the long run, all methods of water measurement must depend upon true principles, and where necessary, proper coefficients will eventually be determined. But even if the principles employed are true, it does not follow that minor errors may not be introduced in isolated cases. Too much attention, therefore, should not be paid to a few scattered observations, particularly when means are not available for checking them.

Author's Closure

This paper on the Research Institute was written at the request of the late Dr. John R. Freeman to form part of a proposed supplement to his treatise, "Hydraulic Laboratory Practice." He had visited the experiment station in the summer of 1930 while the author was spending four months on the Walchensee studying the methods of outdoor hydraulic experimentation. Highly pleased with the spirit and capability of the research staff and with the layout and equipment of the new station, Dr. Freeman felt that his proposed supplementary publication describing more recent laboratory undertakings would be incomplete without extensive mention of the Research Institute.

It will be recalled by those familiar with Dr. Freeman's work that its primary purpose is the detailed description of laboratory layout, equipment, and experimental procedure; results of individual experiments are of secondary importance, as they are generally available in printed form in engineering magazines and

[13] "Water Measurements in Large Power Plants" (Wassermessungen bei Grosskraftanlagen), H. F. Canann, *Wasserkraft Jahrbuch*, 1930–1931.

handbooks. Of similar nature is the interest of a student traveling abroad on such a scholarship as those established by the various Freeman funds to acquaint young American engineers with modern European laboratory technique. Hence the author submitted to Dr. Freeman in the fall of 1930 an extensive description of the Research Institute at Obernach, approved by the institute director, stressing those features of interest to American laboratory men.

Since the proposed supplement to "Hydraulic Laboratory Practice" was not published, Dr. Freeman sent this paper to The American Society of Mechanical Engineers, by which it was printed in the Transactions of May 15, 1932, and then presented formally for discussion at the annual meeting the following December. Judging from the discussion that has been submitted, the primary interests of the readers were neither those of the author nor of his intended audience, for the remarks have been confined almost entirely to the necessarily brief account of certain investigations which were conducted by the Research Institute in the first years of its existence.

Inasmuch as the author is not responsible for the methods of experimentation and interpretation of results (which material was taken directly from publications of the institute), he is not in a position to defend this section of the paper against criticism. However, copies of the various discussions have been sent to the headquarters of the Research Institute at Munich, Germany, in order that the proper authorities would have the opportunity to reply to the numerous criticisms. The following remarks have been prepared under the direction of Dipl.-Ing. B. Esterer, of the Research Institute, and translated from the German by the author:

Comment on the Discussions

Mr. Allen's discussion, paragraph 4. It is obvious that the application of the salt-titration method followed an intensive study of literature on the subject and extensive laboratory investigations, through which the staff of the station had become familiar with the method.

With regard to the Allen method, the Research Institute had gained experience through the experiments at the Walchensee Power Plant, which showed that there was much room for improvement in the way those tests were conducted. Furthermore, for the experiments at Obernach all literature dealing with the Allen method was carefully studied.

If the results of the salt-titration method were better than those of the Allen method, this shows that the former method is easier to apply and control than the salt-velocity method.

Paragraph 5. A detailed description of the experimental layout is to be found in the publications "Vergleichswassermessungen am Walchenseewerk" (Comparative Discharge Measurements at the Walchensee Power Plant), V.D.I., 1930, No. 17, and "Die Genauigkeit einiger Wassermessverfahren" (The Accuracy of Several Methods of Discharge Measurement), V.D.I., 1930, No. 44, which Mr. Allen apparently has not used for his discussion. In the latter publication it is pointed out that a complete description is to follow.

Paragraph 8. It is much to be regretted that, as was afterward apparent, the British Pitometer Company entrusted with carrying out the Allen method did not seem to have sufficient experience with this type of measurement. The very purpose of these experiments was to have the various methods conducted by groups that were completely in charge of the individual methods. Once the British Pitometer Company had taken over these measurements, it was to be assumed that the method would be carried out with due regard to all previous experience.

Each group had the opportunity to arrange its apparatus as dictated by its experience or instructions. At the same time it is evident that due consideration had to be given to local circumstances—for instance, to existing openings in the penstock for installing electrodes etc., to avoid excessive drilling—which is obviously essential in measurements at any power plant in operation.

Paragraph 9. The number of injection valves, their location, and the arrangement and type of electrodes were left to the discretion of the British Pitometer Company. If the arrangement was unsatisfactory to Mr. Allen, this should have been clarified by securing the opinion of Mr. Allen before starting measurements.

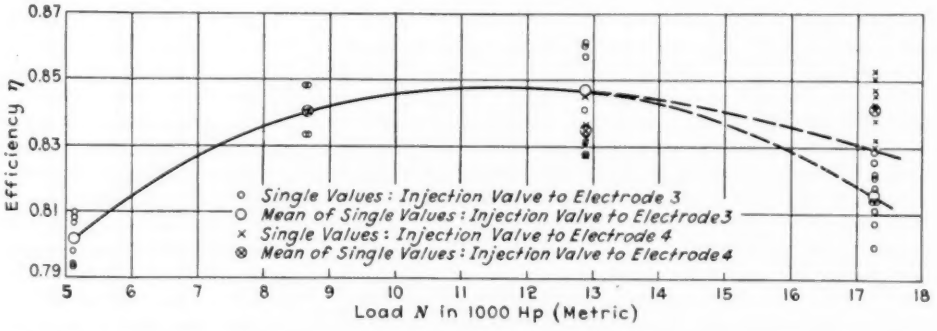

Fig. 23 Comparative Discharge Measurements, Walchensee Turbine Efficiency η Versus Load N (Turbine 6), Salt-Velocity Method

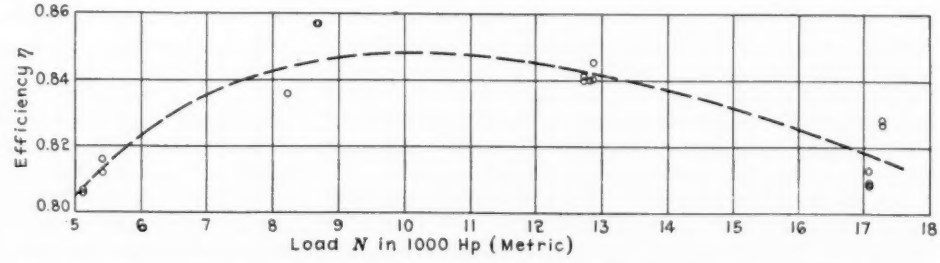

Fig. 24 Comparative Discharge Measurements, Walchensee Turbine Efficiency η Versus Load N (Turbine 6), Current-Meter Method

The arrangement of a number of electrodes along the penstock served the purpose, so far as we know, of determining to what extent the results depend upon the choice of position and interval, since no prior certainty existed as to the most favorable distance between point of injection and electrode.

Paragraph 10. Short electrodes instead of the well-known and time-proved transverse electrodes were used by the British Pitometer Company without further explanation. Hence it was to be assumed that these electrodes had been sufficiently tested for this purpose. The disadvantages resulting from the use

of these short electrodes have been pointed out in the article "Vergleichswassermessungen am Walchenseewerk."

Paragraph 11. The disadvantages of the chosen distances from point of injection to the electrodes are also brought out in the above-mentioned article.

Paragraph 12. It is true that the method of recording the salt curves in the experiments at the Walchensee plant was unfavorable. The Research Institute, therefore, avoided these disadvantages during its own investigations at Obernach by means of the method described in the publication "Die Genauigkeit einiger Wassermessverfahren."

Paragraph 13. Considering the apparatus used for the Allen method, the results must be rated as comparatively poor. It is certain that better results would have been obtained by more satisfactory apparatus; apparently the experience of the British Pitometer was not sufficient to devise at the outset such better apparatus. The results of the Allen method agree so well as they do with the efficiency plot because all results too much in error were omitted and because all values given in the table consist of mean values of the results for the intervals from the injection point to electrode 3 and to electrode 4. At the same time it must be realized that all the results of the current-meter measurements were plotted, without omission of poor values.

In the accompanying two diagrams (Figs. 23 and 24) the results of the Allen salt-velocity method and of the current-meter method, respectively, are plotted to give curves of turbine efficiency against load. In order to show to what extent the individual values for single injections in the Allen method departed from the mean, not only the mean values but also the individual values have been plotted. Similar individual values were also plotted for the current-meter measurements. It is shown that the error for single injections in the Allen method is at least fully as great as for the current meter. Under three-quarters and full load the results for the distances from the injection point to both electrode 3 and electrode 4 were averaged, while under lower loads only the average for the distance to electrode 3 was used. If one draws a curve through the average values for the distance to electrode 3, there results (the lower branch shown in the diagram, Fig. 23) an appreciably greater decrease in efficiency than by using the average value (upper branch) of the means for the two distances. With regard to Table 3 in the article, the following is to be noted: Experiment No. 8 contains an error, to which Mr. Allen calls attention and which unfortunately was not discovered previously. The efficiency should be 84.2 per cent instead of 83.4 per cent. Hence the curve of efficiency for the salt-velocity method is moved upward, near to the curve for the current meter.

Further checking also gave for the Allen method in experiment No. 7 somewhat different values—namely, for the discharge, 2.491 cu m per sec, and for the efficiency, 80.14 per cent. This error occurred through an erroneous mean value in the computation of Mr. Allen.

These corrections and the resulting change in position of the efficiency points will answer a number of Mr. Allen's remarks.

Paragraph 18. In full accord with Mr. Allen's opinion about the use of short electrodes and his suggestion to use instead transverse electrodes, are the remarks in the publication "Vergleichswassermessungen am Walchenseewerk," as was noted in Mr. Allen's further discussion. Concerning Mr. Allen's suggested location of electrodes, it must be noted that in most cases of installation of apparatus one generally does not know how long the expected salt curves will be and hence what position of the electrodes would be most favorable.

Last Paragraph. We add the following to the final remark of Mr. Allen: If the British Pitometer did not apply the method in accordance with the latest developments and all previous experience, this might in part be a result of the fact that it is on the whole very difficult with this method to ascertain at the outset, without lengthy preliminary experiments, the best manner of performance. If this method requires such exceptional experience, then this limits accordingly its field of application. It might thus remain undisputed that insufficient experience existed on the part of the British Pitometer Company; in this case, however, the company should have refused to carry out the measurements. With respect to the publication of complete descriptions and numerical results, it was pointed out in the article "Vergleichswassermessungen am Walchenseewerk" that this was only a preliminary report. It is evident that in the paper of Mr. Rouse on the Research Institute these details had to be condensed even further.

Mr. Billings' discussion, paragraph 3. In the experiments at the Walchensee Power Plant no agreement could be reached whereby the titration method could be used simultaneously with the others. The agreement included only the use of the current-meter and the Allen method for the investigations at the Walchensee.

Paragraph 7. The application of the methods of Allen and Gibson, developed and favored in America, have not yet been introduced in Europe, not because the European engineers are conservative or against these methods, but because the extensive and excellent experience with the current-meter method and the quality of the European meters have not necessitated a departure from this type of measurement.

Mr. Cole's discussion, paragraph 4. It must be admitted that it would have been possible to find a more suitable location for measurement than that chosen; unfortunately local conditions (accessibility and an already existing opening in the penstock, impossibility of rapid reconstruction, and impossibility of interrupting plant operation) made it necessary to conduct the measurements at this position. However, it must be emphasized that the current-meter measurements were conducted under identical flow conditions and that the comparison of the two methods was hence justified.

Paragraph 5. A supporting rod was used for the current meters, but not for the pitometer. The experiments showed, however, that in particular with high velocities, when the pitometer was far inside the penstock, an appreciable vibration of the tube took place, which surely did not improve the accuracy of the readings.

Paragraph 6. An undeniable advantage of the pitometer method is the fact that the velocity can also be measured very near to the walls. To offset this advantage, the difference in head in the U-tube during pitometer measurements at the Walchensee during low discharges was only about 60 mm, so that an error of 2 mm would already amount to 3 per cent. Such an error was easily possible considering the incessant fluctuation of the liquid column. During the larger discharges the difference in head in the U-tube increased to about 300 mm, and the probable error in reading decreased accordingly.

The statement of Mr. Cole that the outer ring of the penstock cross-section, in which region the proximity to the wall made current-meter measurement impossible, amounted to about 12 per cent of the total cross-sectional area, could lead to a mistaken understanding of the resulting error. This error will be comparatively small, because the velocity decreases rapidly in the neighborhood of the wall and because there has been established through comparison with pitot-tube measurements the curve of velocity in this region.

For the experiments at the Walchensee plant the flow near the boundary was determined from the equation

$$v = v_o \left[1 - \left(\frac{r}{R}\right)^n\right]^{1/7}$$

with $n = 3$ (v_o represents the velocity at the center). By using values of $n = 4$ and 5 to determine the form of the curve at the wall, the discharge would be changed by only 0.05 to 0.1 per cent.

Paragraph 7. The pitometer responds just as rapidly to variations in velocity as the current meter; the basic difference lies, however, in the fact that the current meter yields an integrative measurement of the fluctuations, while the pitometer shows instantaneous values and the fluctuations in velocity give rise to disturbing oscillations in the U-tube and a decreased accuracy in reading.

Paragraph 8. This conclusion in Dr. Kirschmer's original report is not based upon the assumption of a constant pitometer coefficient, but on the contrary was derived from Fig. 19 of his report. From this diagram it is evident that in the measurements at the Walchensee the pitometer gave too high values for small discharges.

Paragraph 11. Although the current-meter measurement No. 8 showed an appreciably higher efficiency than measurement No. 1 for a somewhat smaller load, no reason could be found to believe that an error in measurement had been made. Against such an error stands the fact that No. 8 consisted of two single measurements, which both gave exactly the same rate of discharge.

Mr. Mousson's discussion, paragraph 6. The very fact that the British Pitometer Company was entrusted with conducting the Allen method should have been a guarantee that this method would be carried out by a personnel theoretically and practically familiar with it. It is to be regretted exceedingly that this supposition was not justified to a sufficient extent. The experiments with the Gibson method were conducted at this time in order to try out a new pressure recorder that had been designed by Dipl.-Ing. Volkhardt under the direction of Professor Thoma. Since then Volkhardt has described this apparatus and further experiments with it in Publication No. 6 of the Mitteilungen des Hydraulischen Instituts der Technischen Hochschule, Munich.

Paragraph 9. In order to avoid confusion, it must be understood that the further discussion of Mr. Mousson deals not with the experiments at the Walchensee, but with the measurements at the experiment station in Obernach; the latter results were published in the article, "Die Genauigkeit einiger Wassermessverfahren."

Paragraph 13. The derivations of Mr. Mousson provide a logical and very welcome explanation for the results of the measurements at Obernach. It is necessary, however, to test these derivations very scrupulously. The Research Institute repeated the experiments in 1931 with the same Ott meters as in 1930, with results that depart appreciably from those of 1930.

Instead of a mean departure for the spoke-vane Ott meter of —0.56 per cent, this value became —0.78 per cent, and for the conical-screw propeller instead of —0.30 per cent a departure of +0.39 per cent from the results of the measuring basin, despite the fact that the measurements were again conducted with the greatest care. The investigations were extended to include the maximum discharge possible in the canal, with a velocity of 1.7 m per sec. An asymptotic approach of the variations to a constant value with increasing velocity could not be determined in these experiments with the conical-screw meter.

Unfortunately the investigations had to be discontinued because of more pressing matters. Since a further check has not as yet been possible, the results are mentioned only provisionally. These experiments will be continued this year, at which time the variation noticed in 1931 will be checked and a thorough investigation will be made along the lines discussed by Mr. Mousson.

Paragraph 15. It is not probable that the results of the Type I current meter were influenced by the presence of algae or similar material caught in the spokes, since the meter was watched constantly to avoid just this occurrence.

Paragraph 29. In order to reduce to a minimum the errors which could occur during the current-meter runs, the head at the measuring weir was recorded continuously. If the average head during the time of the current-meter measurement did not correspond exactly with that at the time of filling the measuring basin, then the results of the basin measurement were corrected according to the $^3/_2$ power of the head on the weir.

Contrary to general practice, the measurements were carried out with one meter at a time, because only one Price meter was available and all meters were to be tested under identical conditions.

Paragraph 32. Measurement of the velocity curve in the immediate neighborhood of the channel walls was omitted for the following reasons:

1 The accuracy of customary meter measurements was to be determined—not for cases in which special means for increasing the accuracy are employed.

2 The form of the curve in the neighborhood of the walls is sufficiently well known under normal conditions of flow (seventh-root law), so that plotting the transition near the wall and floor can be undertaken with all desired accuracy.

3 Through measured points the form of the curve is determined to such an extent that in drawing the transition curve to the wall not much freedom remains. Outward displacement of the velocity curve at one point usually calls for an inward displacement in the neighboring section, through which the differences in area are counterbalanced. From several trial diagrams of the velocity distribution it was found that changes in the curve near the walls would not change the result by even 0.1 per cent.

4 Even when the form of the velocity curves at the boundaries of the individual horizontal or vertical sections has been determined exactly, there still remains a certain amount of discretion and uncertainty in determining the boundary transitions for the summation curve of all the individual sections.

Paragraph 33. Again it must be emphasized that at the Walchensee as well it was not a matter of conducting the meter measurements in an especially refined manner, but in the customary way, and then of comparing these results with those of the other methods. Hence the measurements of velocity were undertaken across a single diameter.

Paragraph 36. The exceptionally good agreement of the ratings of the Bureau of Standards with those of Dr. Ott is remarkable, but should not, however, lead to discontinuing the study of rating accuracy and agreement between results of various stations. It is true that the results of different stations show discrepancies principally at low velocities and approach the same value as the velocities increase. Nevertheless, this range is rather great, so that for a velocity of about 1.5 m per sec differences up to 1.5 per cent have been determined in different rating stations—although for other types of meter than those used by the Research Institute.

Paragraph 39. The way pointed out by Mr. Mousson of increasing the accuracy of meter measurement through use of the two-type current-meter method is especially worthy of notice. There are surely many instances in which one will undertake the necessary duplication of apparatus and increase in time for measurement and computation, when it is essential to reach a particularly high degree of precision.

Dr. Ott's discussion, last paragraph. In agreement with the following discussion by Mr. Pierce, it may be added at this point that the newer Gurley-Price meter is apparently greatly improved and also more suitable for measurements over comparatively small cross-sections—as, for instance, in the canal used by the Research Institute. In the summer of 1931 measurements were conducted by the Institute with the Gurley-Price meter No. 622 mentioned by Dr. Ott, with a mean departure (based on 20 single

measurements) of —0.6 per cent from the result of the measuring basin, while with the old model Price meter in the experiments of 1930 a departure of +1.84 per cent was determined. This result was obtained in the long, straight experimental canal of the Research Institute under conceivably favorable conditions. However, this result is given only provisionally at this time, since the experiments, as already mentioned, were not completed, and in particular were not controlled through subsequent rating of the meters. How the new Price meter agrees with basin measurements in turbulent flow and under various conditions of angularity is to be investigated through measurements this summer. Even the new type of Price meter showed during rating appreciable variation when towed near the left and right walls and near the surface and channel bottom. In plotting the results for a horizontal section, the velocities near the one wall were greater and the velocities near the other wall less than those measured with the Ott meters. The accompanying differences in area as compared with the Ott curves, however, nearly counterbalanced each other.

A welcome and practically valuable problem to investigate would be a study of the characteristics of various meters in flow such that the velocity varies greatly across the width of the meter—as is the case, for instance, in the neighborhood of channel walls.

Mr. Rheingans' discussion, paragraph 6. Recording the salt-velocity curves by means of a spark was decided upon after extensive preliminary experimentation. Use of the customary recording apparatus with pen and ink showed a lag in comparison with records of an optically registering oscillograph, as well during rise as during fall, which would seem to be a result of the friction of the pen on the paper and the viscosity of the ink. Such frictional restriction is avoided through use of a sparking apparatus. The tiny punctures left by the sparks in the paper record lie with very slight scattering on either side of an easily constructed mean curve. In the case of the size of diagram used by the institute (about 100 mm in height), the error due to this scattering effect would probably be less than that due to the frictional lag of the pen.

It was impossible to explain this great negative variation (see latter part of paragraph 6) through error in measurement of the time of injection, since the time record was controlled automatically by the opening and closing of the valve on the injection pipe and also registered automatically by means of a recording amperemeter. It is certain, however, that at every injection into the open canal there resulted a disturbance of the flow, a sudden backwater effect, which was noticeable on the surface and probably gave rise to the strong negative error in time for every measurement beginning at the point of injection. In closed pipe lines flowing full this source of error becomes practically negligible, since the momentum of the injected liquid is very small in comparison with that of the flow in the pipe. Hence there is hardly room for contradiction of the statement, based upon the experiments at Obernach, that the Allen method is less suitable for open channels and despite the greatest care is subject to more errors than when used for flow in closed pipe lines.

Paragraph 9. An essential prerequisite for the titration method is the existence of a strongly turbulent flow. The manner of flow at the sampling station is of no concern. The high efficiency of modern turbines generally precludes the probability of strongly turbulent movement of the water through the turbine. Hence the titration method is confined principally to measurements in mountain streams etc., as is noted in the article "Die Genauigkeit einiger Wassermessverfahren." In just such important cases the use of current meters is far inferior to the titration method, and the latter often affords the only possibility of a practical means of measurement. The Research Institute has conducted a great number of such measurements, described in the publication of Dr. Kirschmer, "Das Salzverdünnungsverfahren für Wassermessungen" (The Salt-Dilution Method for Water Measurements), *Wasserkraft und Wasserwirtschaft*, 1931, No. 18.

For discharge measurement of turbines the use of the titration method is limited to special cases in which thorough mixing is certain to occur—for instance, in Pelton wheels, in the waste pipes of which complete mixing almost always takes place. In such cases good results have already been obtained, as is also noted in the foregoing publication of Dr. Kirschmer. If the necessary high degree of turbulence is not present to a sufficient extent at a power plant, favorable results can still be obtained through particular care to distribute the injected salt solution. Through the extensive apparatus necessary for such a case, and through the great number of samples which must be taken, the principal advantage of this method, namely, its simplicity, is lost.

Paragraph 11. This criticism concerns the company which conducted the Allen method at the Walchensee plant. As already mentioned, it was a matter of handling the current-meter measurements at the Walchensee plant as it is customarily done in penstocks in Germany, and to compare this method with the others. Hence measurements were made across a single diameter.

Paragraph 13. Through correction of the efficiency for run No. 8 (Allen) the agreement of the efficiency curves for the current-meter and the Allen methods was improved considerably. Next to the too low values of the efficiency as measured by pitometer under the smallest load, also established by Mr. Cole, the great scattering of both pitometer measurements under the greatest load is to be emphasized, which makes a difference of about 4 per cent of efficiency. Hence it could be considered more as a coincidence that the mean of these two measurements agrees with the result of the Allen method at this load. The efficiency points at three-quarters load for pitometer and current meter are within less than 0.5 per cent from each other, while at one-half load the pitometer results lie from about 1 to 1.5 per cent lower than those of the current meter, and also from about 0.3 to 0.9 per cent below those of the Allen method. The two accompanying diagrams (Figs. 23 and 24) show that the efficiency curve for the current meter up to a load of about 11,000 hp lies higher than the efficiency curve for the Allen method, and lower from there on. The value of the maximum efficiency is about the same. Under these conditions it cannot be a matter of favoring the current-meter results as expressed by Mr. Rheingans in his sentence, "Since the current meter gave . . . ."

Paragraph 14. In the article, "Vergleichswassermessungen am Walchenseewerk," further details are given concerning the manner in which pressure differences were measured for the pitometer. The transformation of the differences in head into velocities was not accomplished on the basis of pitometer coefficients, but through use of rating curves of the British Pitometer Company.

General Comment

The author wishes to express the hope that the foregoing translation will be satisfactory to the Research Institute in Munich; unfortunately both the discussion and its translation had to be undertaken in an extremely short space of time.

It is obvious that such discussion as has been submitted could continue indefinitely. The only remedy seems to lie in the following suggestion of Mr. Sigmund J. Bitterli, quoted from his article, "Making Water Measurements With Current Meters" (*Power*, January 19, 1932):

"Methods of making acceptance tests in Europe differ distinctly from those used in America. Each method possesses its particular advantages, but has peculiarities that must be

mastered before satisfactory results may be obtained. Unfortunately there exists considerable prejudice on the two continents against the use of testing methods that have apparently given satisfaction in the other. It is desirable therefore that truly comparative tests could be made.

"Various attempts to secure comparative results have been made. As each method requires the technique of those who are familiar with their own methods, such comparisons cannot be successfully made unless the respective experts can be present in the field. It is hoped, therefore, that such tests can be made either in America or Europe, with the advocates of the various methods actually present."

Progress in Iron and Steel

THE rate of pig-iron production for the year of 1932, to date, has been unprecedentedly low, if judged by twentieth-century records. One must turn back to 1898, 35 years ago, to find an annual production less than the 10,162,776 tons that will be produced in 1932 if the output for the first six months, of 5,081,388 tons, is a proper criterion of what is to follow for the remainder of the year.

By any comparison the showing for the first half of the current year is a sorry one. It is only 56.5 per cent of the 17,957,779-ton rate of 1931 and only 46 per cent of the 11,022,349 tons produced in the first half, the corresponding period, of 1931; and no one was bragging about production in 1931. Compared with the previous 10-year average of 33,955,000 tons, the rate for the first half of 1932 was 30 per cent.

Combined open-hearth and bessemer steel ingot output for the first half of 1932 is estimated at 7,567,769 tons, or at the rate of 15,135,000 tons per year, as compared with 25,193,000 tons in 1931, or 60.3 per cent of last year's rate. It is about 36 per cent of the previous 10-year average.

Both pig-iron and steel operations were at record low percentages as compared with potential capacities.

Tonnage output alone, however, is by no means a complete measure of progress in the industry, and it would be unfortunate indeed if the unusual opportunities afforded by this period of abnormally low rate of furnace and mill operation were not marked by a considerable advancement, at least in the technical and economic phases of iron and steel manufacture. It is true that the necessity for conserving cash resources has prevented large expenditure for plant improvements, and except for work started during or shortly after the prosperous period of 1927 to 1929, there has been no expansion in capacity worthy of mention. One does not look in vain, however, for evidence of successful effort along the lines of raw-material preparation and handling, equipment manufacture, plant design, and operating methods.

As a matter of fact, the exigencies of the depression have greatly stimulated the interest of steel-plant executives in the study of ways and means to increase profits by other procedures than increasing output capacity, which long-continued policy has undoubtedly had something to do with the present lopsided relationship between supply and demand and which in turn is leaving many manufacturers with an almost unsupportable burden of fixed interest and depreciation charges on idle plants. At any rate, it is now thoroughly realized and appreciated that increase of profits by reduction of costs is a wiser method, and during the past year there has been a tremendous amount of investigation, study, and planning with this end in view.

The full measure of what is being accomplished cannot be taken until a resumption of more nearly normal operations permits a fuller application of methods and equipment now being developed, but the following reports prepared by engineers who specialize in and are closely in touch with the several branches of the industry enumerate and comment on some of the more promising new developments.

Presented at the second session of the Iron and Steel Division, Monday afternoon, December 5, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Compiled by William A. Haven and William C. Buell, Jr., of the Iron and Steel Division, from material furnished by D. C. Agar, R. P. Balph, William C. Buell, Jr., A. L. Foell, William A. Haven, Stanley H. McKee, W. G. Swart, and C. B. Thorne.

Personnel of the Executive Committee of the Iron and Steel Division for 1932: Arthur G. McKee, Chairman; J. H. Hitchcock, Secretary; W. Trinks, A. J. Boynton, W. A. James, W. R. Webster. Associates: C. S. Robinson, G. T. Snyder, F. C. Biggert, Jr., F. G. Cutler, Willis McKee, S. M. Marshall, R. L. Streeter. W. W. Macon.

BLAST FURNACES

Some of the most interesting developments in pig-iron manufacture during the last year are to be found in operating practices that were originally considered purely emergency measures, but that are now being hailed as permanent improvements. The most important of these has been "slow blowing."

To the experienced blast-furnace operator the advantages to be derived from a careful adjustment of blast volume to the size and design of the furnace and particularly to the quality of raw materials have always been realized. The trend to large 1000-ton furnaces, as the writer pointed out in an article published in 1926, could scarcely have been justified on the basis of increased productivity alone. Careful observers at that time were fully aware of the fact that one of the chief virtues of the large units was their ability to turn out a required tonnage without being forced to take an amount of blast out of proportion to the volume capacity of the stack. There was always previously, however, a great pressure exerted upon operators to squeeze the maximum possible tonnage out of every existing unit. Recently, the pressure from the plant management has been to get as little tonnage as possible, while keeping the furnace in operation as a vital link in the chain of steel-plant manufacture, not only for making the requisite amount of hot molten metal, but as a producer of gas upon which the manufacture of coke and coke-oven gas, the generation of power, and the heating of metallurgical furnaces are largely dependent.

This situation has resulted in "slow blowing," or blowing the furnace at a rate somewhere below the point of maximum production. Blast volumes were gradually reduced to keep pace with the operation of other departments. This was not done entirely without reluctance and opposition on the part of the furnace operators, for furnace men have been trained and tuned up to the policy of large production, which means heavy blowing. Many had anticipated serious operating difficulties from building up of hearth, bosh, and stack, with resultant hanging and checking, but these were not encountered. On the other hand, surprisingly good results followed. Flue-dust losses were substantially reduced, coke consumption was decreased, and the quality of the iron became more regular and better.

With the demand for tonnage declining over a period of almost three years, it naturally followed that the advantages derived from slow blowing should be pressed to the utmost, and today we have many instances of stacks being driven at only about one-half of what was considered their normal rate. The figures of Table 1 are typical.

TABLE 1

	Normal operation	Slow blowing
Cubic feet of wind, per minute	48,000	25,000
Tons, per day	762	372
Coke, per ton	1,638	1,707
Amount of scrap used, per cent	12.6	None
Flue dust produced, pounds per ton of pig	353	111
Loss of metallic, per cent	6.50	0.33
Off-sulphur iron, per cent	0.36	None

An examination of these figures discloses the tremendous reduction of losses that can be accomplished if gas velocities through the furnace are kept at a minimum. Notwithstanding the denser burden brought about by discontinuation in the use of scrap, the flue-dust losses were cut to one-third of their previous

figure. Such results are of course only accomplished with excellent furnace supervision, but the case under consideration is one of many. At another furnace in the same plant flue-dust losses were reduced 80 per cent, and at many other plants throughout the country we now find less than 100 lb of dust being made per ton of pig. Such a small amount of flue dust can feasibly and economically be returned to the furnaces without benefit of sintering.

The thermal efficiency of the operations shown in Table 1 likewise speaks well for slow blowing, if due consideration is given to the amounts of scrap consumed. Given an equal amount of scrap in the burden, the advantage in slow blowing would have been not less than 200 lb of coke per ton of pig iron. It is interesting to notice that even with the extremely low scrap prices prevailing, many companies have found it desirable to conserve their cash by reducing stocks of ore on hand, particularly since by slow blowing such a complete recovery of the metal in the ore can be effected.

The adverse results of slow blowing are of course higher labor costs and higher fixed charges, which are directly proportional to tonnage. But even at a 50 per cent rate, the net effect in many cases has been a final cost of pig iron which is as low or even less than that obtained by so-called normal operations. From this we may rest assured that after the demand for iron returns there will be a great effort made to find the rate of blowing that will produce the maximum of profit for the plant rather than the maximum output.

Associated with slow blowing, as a means of keeping blast-furnace production in step with hot-metal requirements, is intermittent operation. Here the results, while not so productive of economies as slow blowing, have furnished some surprising upsets to former accepted theories.

Short periods of banking, especially over the week end, had been tried many times in the past, but with such unsatisfactory results as to discourage any regular procedure of this nature. Intermittent operation as now practiced was probably first suggested by the advantages of week-end banking, but in the past year a technique of performance has been developed that far surpasses anything previously employed. Instead of a complete shutdown of the furnace, a slight blowing is kept up—for characterization of which a new word, "fanning," has been coined. In the past, fanning a furnace was something that operators were prone to avoid, most of them preferring a complete shutdown, for the same reasons that have been listed against slow blowing.

Now, however, the beneficial effects of fanning, as compared with complete stoppage, are becoming apparent. Fanning keeps the hearth hot, probably has a tendency to keep the furnace walls clean, eliminates the necessity of purging the mains, and accomplishes a considerable amount of "predigestion" of the stock, which greatly facilitates easy resumption of blowing. In this way the necessity of coke blanks is avoided, and operations are carried on with a rather amazing thermal efficiency.

Almost any combination of blowing and fanning periods can be worked out, either to meet the tonnage requirements or to accommodate periodic demands for hot metal. In almost every case, however, it would seem on the basis of theory that the best results would obtain when the period of blowing is not longer than will be required to empty the furnace of stock "predigested" by fanning; and in practice this procedure is generally followed. From 4 to 12 hours' blowing, alternated with periods of fanning of from 4 to 20 hours in duration, covers most of the cases with which the writer is familiar.

In general, the lesser advantages from intermittent operation lead to the use of continuous slow blowing where conditions are such as to make the method of reducing production optional, and this is in spite of the fact that during the fanning period a complete laying off of the operating force, with the exception perhaps of one foreman or water tender, is generally followed. As with slow blowing, however, it may be stated with assurance that intermittent operation has been so successfully worked out in practice that it may be considered a permanent contribution to the art and one that will at times be utilized to advantage after the depression is behind us.

Reference has been made to the tendency of producing companies to conserve cash expenditures by the elimination of purchased scrap from the furnace mixtures. The unprecedentedly low prices of scrap materials, however, have made it economically desirable, if other conditions permit, to use large proportions of scrap, and in a few cases advantage has been taken of this unusual situation. It has been interesting to note just how much scrap could be carried without interfering with the smooth working of the furnace. One case is of record where 1130 lb of scrap per ton of pig was used for a period of several weeks. The feasibility of using large quantities of scrap has a great bearing on the relative cost of producing iron in the several large producing centers, and the low scrap prices that have prevailed during the past year have further accentuated the continually growing differential in material assembly costs in favor of the Detroit and Chicago districts.

During the past several years there has been a growing interest in the more profitable utilization of blast-furnace gas. Following the pioneer installations at the Hamilton, Ont., plants of the Steel Company of Canada, a number of American concerns have successfully applied blast-furnace gas to the heating of soaking pits and heating furnaces, and in some cases, mixed with coke-oven gas, to open-hearth practice. The year of 1932 has seen only a little extension in this practice, but at one more plant at least blast-furnace gas has been used for heating by-product coke ovens.

These uses of blast-furnace gas are not new, but they are leading to some interesting developments in the way of equipment for the more economical and thorough cleaning of blast-furnace gas and its conservation by improving the efficiency of hot-blast stoves. Up until this year the only proved dependable method of thoroughly cleaning blast-furnace gas has been by means of Theisen washers or mechanical scrubbers of the disintegrator type. Mechanical scrubbers have had several objectionable features, chief among which may be mentioned the high cost of operation and the inability to dry the gas. The use of disintegrators has also brought about an additional hazard in handling gas.

In a paper read before the A.S.M.E. in 1930, it was pointed out that the successful development of a wet electrical precipitation method would accomplish a solution of the problems that the disintegrator had failed to meet in a satisfactory manner. Subsequently there has been a very active application of attention to the perfection of the electric cleaner, stimulated no doubt by the fact that the basic patents on the precipitation principle have recently expired, and 1932 has been marked by satisfactory installations of at least two electric cleaners of distinctly different design. When it is understood that the power consumption by the electric method is only about one-tenth that of mechanical scrubbing and that dry gas, cleaner than 0.01 grain per cubic foot, is obtainable, the importance of this development may be readily appreciated.

In at least one type of electric cleaner the final cleaning apparatus may be combined with the primary washer to form a single compact unit, thus saving valuable space and simplifying the entire cleaning system which with its various units, pipes, and fittings had begun to take up more room than the furnace or stoves. We may look for a rapid application of this type of

cleaner, which promises to save about $8^1/_2$ cents per 100,000 ft of gas cleaned, or approximately $10^1/_2$ cents per ton of pig iron produced.

For the conservation of gas and the attainment of higher blast temperatures the year has been marked by the introduction or at least the placing on the market of additional types of stove checkers designed for the purpose of more rapid and efficient exchange of heat between gases and blast. In keeping with the spirit of the times the advantageous utilization of clean gas by increasing the heating surface and heating capacity of existing stoves without removal of the old checker work has received particular attention. One of the most novel and promising developments in this connection has been the design of spheroidal-shaped refractories for insertion in old checker flues, when areas are unnecessarily and wastefully large for using thoroughly clean gas. Inserts of this type will obviously solve the hitherto impractical if not impossible job of getting them into the flues without dismantling the old checkers. At any rate, 1932 has witnessed in this development another promising innovation.

There have been some new developments in the design of slag and hot-metal handling equipment, noteworthy among the latter being ladles of all-rolled and welded steel construction that have the advantages of being lighter and probably of lower first cost. Development of better refractories for blast furnaces and stoves continues, with a trend toward high-alumina brick for service where extremely hot gases have to be handled.

A new type of dust catcher utilizing a zeppelin or streamline principle for more equal distribution of gas and prevention of turbulence has been designed and built; double-compartment bosh and stack plates applying the advantages of double-compartment tuyères to the cooling of furnace walls have been brought on the market.

The rapid growth of and the demand for cheap forms of insulating material have revived the manufacture of slag wool, and considerable success has attended at least one progressive plant in the development of new methods for perfecting this process and improving the quality of the product.

All in all, blast-furnace designers and operators may take pride in their strenuous efforts to make the best of what has been, so far as output is concerned, the worst year that the industry has had in a generation, and find satisfaction in the fact that for them the period of the depression has been by no means devoid of progress along technological lines.

Lake Superior Iron Ore

During the last 20 years (1912 to 1931, inclusive) the Lake Superior district has produced approximately 84 per cent of the iron ore mined in the United States. Its record is shown in Table 2.

TABLE 2

5-Year period	Total tons shipped	Average tonnage per year
1912–1916.....	245,912,511	49,182,502
1917–1921.....	259,825,024	51,965,005
1922–1926.....	264,215,238	52,843,047
1927–1931.....	244,040,988	48,808,198
20 years.....	1,013,993,761	50,699,688

Peak year, 1916, 66,672,881 tons shipped
Peak year, 1929, 66,157,359 tons shipped
Low year, 1921, 22,851,995 tons shipped
Low year, 1931, 23,496,228 tons shipped

Districts in the United States other than Lake Superior have averaged about 10,000,000 tons' annual production over the last 15 years.

The average analysis of Lake Superior shipments does not vary much from year to year, as shown in Table 3.

TABLE 3

Year	Iron (natural), per cent	Phosphorus, per cent	Silica, per cent	Manganese, per cent	Moisture, per cent
1922....	51.87	0.099	8.23	0.76	10.78
1931....	51.53	0.087	8.60	0.80	10.84

Such uniformity is not a natural phenomenon, but is maintained only by a system of careful mixing or grading, which operation provides one of the problems constantly faced by the mine operator. To many people iron ore is simply iron ore, but the steel maker demands many varieties or grades. Most iron mines are able, by selective mining, to produce more than one grade, and in some cases the output of several mines is combined to form desired grades, each suitable for some special purpose.

There is a small but growing demand for ore of better analysis than the average, for making special quality steels. Beyond doubt the present average analysis, as shown, can be and will be maintained for a long period.

The year 1932 cannot be fitted into any previous picture. With the steel production of the country down to around 20 per cent of capacity, there is ore enough in reserve at the furnaces and Lower Lake docks, carried down in 1930 and 1931, to last for two years at the 20 per cent rate. No ore need go down the Lakes this year, and but little will. Every mine that can close down is idle.

During the last 20 years the production of steel has increased greatly, although, as shown in Table 2, iron-ore production has not. This is largely due to the increased use of scrap metal in the open-hearth process, present practice being estimated to call for about 40 per cent scrap in the charge.

Predictions made 15 to 20 years ago that iron-ore requirements from Lake Superior would rise to 75,000,000 tons or more annually have not been borne out, nor are they likely to be.

The Lake Superior region is beyond doubt equipped with mining and transportation facilities for an annual production of 75,000,000 tons or more, but as far as can now be seen the average future demand is not likely to exceed 60,000,000 tons. At this lower rate the merchantable reserves of the district promise a life of between 20 and 30 years, but back of the merchantable reserves are enormous tonnages of low-grade material, which it has already been demonstrated can be brought up to merchantable grade by various beneficiation processes, such as drying, washing, jigging, tabling, crushing, screening, sorting, flotation, magnetic separation, sintering, and direct reduction. Improvements in such methods are fairly rapid at present, as is evidenced by the fact that in 1930 about 40 per cent of all iron ore shipped from Minnesota had been beneficiated in some way.

These recent years have also seen great improvement in mining methods, outstanding among which are electrification of both open-pit and underground mines, the use of larger electrified shovels on caterpillar mounting and electric haulage in the open pits, and the use of scrapers underground, all of which have been fully described and discussed in the technical press. The importance of these changes is indicated by the fact that in Minnesota today 9000 men produce what formerly required 21,000.

In considering such statistics as those given herein, it should always be kept in mind that the output of iron mines is not free either as to tonnage or grade, but is strictly controlled by the quantity and quality of iron and steel that can be marketed. This has been a strong factor in one important change in the situation. Formerly a large part of the ore was mined and sold by independent operators. More ore was always offered than could be sold. Today by far the greater part is controlled and mined, directly or indirectly, by consuming interests, the steelmakers themselves. The independent market has practically disappeared.

The situation may perhaps be summed up by saying that Lake Superior reserves of raw material are very large and will be competitive even when beneficiation is more of a necessity than at present. Increases in output can readily be met if demanded, at any time. Direct operating costs can probably not be much reduced, but overhead items can and will be lowered, when that becomes essential to meet imported ore at Lower Lake ports.

Coke Ovens

There are at present in the United States, in operation or capable of operation, 13,727 by-product coke ovens, with an aggregate coke-producing capacity of approximately 5,000,000 net tons per month.

From a production of 3,602,000 net tons of furnace coke in by-product coke ovens in August, 1929, production in the United States declined to a low of 958,000 tons of furnace coke in May, 1932, or 27 per cent of the 1929 peak. It follows that unless finished-steel production declines at exactly the same rate as coke production, major problems in flexibility in the use of coke-oven gas for steel-plant heating purposes will arise. Variations in the ratio of coke to finished steel are intensified by the fact that many steel companies turn out plates, sheets, and other finished products on an immediate demand basis and do not average out production to any considerable extent by anticipating future orders.

A development in coke-oven technology that was inaugurated in America toward the end of the last decade is the underfiring of coke ovens with blast-furnace gas. This development coordinates the operation of coke plants with heat application in steel plants and provides flexibility in the use of gas in keeping with abnormal steel-plant operations. An excellent paper on this subject was prepared by Charles R. Meissner, superintendent of the by-product coke plant of the Weirton Steel Company, and Julius H. Strassburger, assistant chief engineer of the Weirton Steel Company, and was presented before the American Iron and Steel Institute at New York on May 19, 1932. The fine results from the use of blast-furnace gas in coke ovens are fully set forth in that paper.

Open-Hearth Plant

In common with all other plants of American industry, the open-hearth plant has been called upon during the current year to supply fractional capacity at costs far below any figures approached during the last 20 years. When it is considered that the ingot capacity of the United States is about 67,500,000 tons and that but 25,000,000 tons was produced in 1931, representing 37 per cent, and but 7,500,000 tons in the first half of 1932, indicating a rate of probably less than 22 per cent for the entire year, it is simple to picture the condition of this division of industry, which, from the enlarged units of the past decade, depends on high production rates for its profitable operation.

The newer plants with furnaces of larger size, other than in one or two exceptional instances, have been badly handicapped in producing the small tonnages ordered to the competitive analyses specified at a cost that would show a profit while the older plants with smaller furnaces have had a considerable advantage from the operating and cost standpoints.

A small plant, a component of one of the larger producers, with 50-ton furnaces, operating without hot metal, has been able to consistently show the lowest ingot cost of any of the plants of this group during the last 20 months. Further, this plant is operating intermittently by crude methods and without any of the more modern appurtenances of operation.

For several months following the beginning of the current depression, most of the steel companies went forward with substantial apparatus and practice research programs that promised much. Since the first of the present year, these programs have been severely curtailed or entirely omitted, with the unfortunate result that little or no research in these directions is now being carried on.

However, several furnaces have been equipped for their automatic reversal from temperature difference, and a few installations of combustion or draft control have been made.

One of the larger companies has been experimenting for a number of months with a method of firing the furnace through the roof, the flame being directed generally downward and toward the backwall. This experiment is being conducted with considerable secrecy, but it is understood that the time of heat is materially shortened with some fuel, and with a considerable metal savings as a result of using the method.

Another method involving the firing of the furnace from four points is being introduced, but it will probably be some time before definite results will be available for comment.

The successful conclusion of either of these methods would mark the first radical change of open-hearth practice since the days of Siemen and Marten.

Research in the metallurgy of the process has been continued in part, particularly in deoxidation, and progress appears to have been made. Progress is of necessity in detail, and no startling developments in the metallurgy are to be expected. The manufacturers of refractories have made marked improvements in these products, and as furnaces are in time operated to the end of their life and rebuilt, it is expected a material lengthening of furnace life will result.

The meetings of the two larger groups of open-hearth superintendents for the exchange of experience and ideas have been well attended during the past year, but in one of these groups at least much time is wasted in a discussion of smaller details that, while usable in a plant here or there, have no general application. However, considerable good comes from these meetings, and the appreciable increase in the number of younger, technically trained men who are working into the superintendencies of these plants augurs well for future progress.

Rolling Mills

While progress and development in the art of rolling steel have necessarily been seriously curtailed due to the extreme inactivity in operations during the past year, the period has nevertheless been marked by the completion of a number of large mill installations and several distinctly new developments.

Notable among the mills completed during the year are the wide-flange beam mill at the Illinois Steel Company, the continuous plate and sheet strip mill at the Inland Steel Company, and the continuous sheet strip mill at the Otis Steel Company. These installations in the aggregate have an additional annual producing capacity of approximately 1,750,000 tons of finished and semi-finished products.

The wide-flange beam mill was designed to produce wide-flange structural shapes from 8 to 36 in. in depth, with flanges from 6 to 15 in. in width, and weighing from 21 to 425 lb per ft. The mill was installed at the South Chicago Works of the Illinois Steel Company. The facilities consist of a 54-in. reversing blooming-mill stand, a 52-in. reversing roughing-mill stand, a 52-in. intermediate reversing stand, and a 52-in. single-pass finishing stand, all motor driven, together with a full complement of soaking pits, mill tables, cranes, reheating furnaces, bloom shear, hot saws, and cooling beds.

The continuous plate and sheet strip mill installed by the Inland Steel Company at Indiana Harbor is designed to roll universal plate from $^3/_{16}$ in. to $^1/_2$ in. in thickness up to 69 in. in width and the usual gages and grades of sheet, hot- and cold-rolled strip in widths from 6 to 66 in. The mill comprises three

slab reheating furnaces and ten four-high mill stands, of which the first stand has 36 × 49 × 96-in. rolls, the next three are universal stands with 25 × 49 × 77-in. rolls, and six finishing stands having 24½ × 49 × 77-in. rolls, together with two scale breakers all separately motor driven. The mill further includes complete finishing equipment consisting of cooling beds, transfers, tables, coilers, levelers, shears, etc., as required for the various classes of product rolled.

The continuous strip mill built and placed in operation by the Otis Steel Company at its Riverside Works in Cleveland, Ohio, is capable of producing plate, strip and strip sheets from 18 gage and heavier in thickness and 24 to 65 in. in width. The mill is placed in direct line of production with an existing 40-in. blooming mill, from which slabs can be rolled direct or reheated and rolled after passing through either of two reheating furnaces, and so arranged as to permit independent operation of either mill when desired. The mill stands are 10 in number, of which the roughing stands are two-high, having 32 × 72-in. rolls, and five are four-high finishing stands, with 20½ × 45 × 72-in. rolls. There are four edging stands in the roughing mill line. All roll stands are individually motor driven. The mill is further equipped with cooling beds, coilers, flying shears, and plate-piling machinery to handle both finished and semi-finished products, either in coils or flat plate. Two stands of cold rolls were also installed, each with 20½ × 52 × 72-in. rolls to cold-finish product from the continuous mills.

The latest development in the hot rolling of flat material and strip has been successfully demonstrated this year by the Cold Metal Process Company on an experimentally equipped Steckel hot mill located at the Brier Hill Plant of the Youngstown Sheet and Tube Company at Youngstown, Ohio.

One mill stand of four-high rolls, having 20-in.-diameter work rolls and 36-in.-diameter backing-up rolls, all 72 in. in length, is used. This stand is served by two elevated hot-coiling furnaces, one spanning the approach table and the other the delivery table, each approximately 14 ft from the center line of the mill stand. Each hot-coiling furnace has a 48-in.-diameter reel made of heat-resisting alloy steel. The purpose of these furnaces is to maintain a rolling temperature in the strip after the slab reaches the thinner gages.

During the demonstrations that took place at various times this year, slabs 3 and 4 in. thick, 9 ft long, and up to 36 in. wide were used as raw material. Each slab, heated to 1600 to 1800 F, was brought from a slab-heating furnace by crane, deposited on the approach table leading to the mill, and run through a scale breaker, equipped with steel brushes to loosen the scale on the top and bottom surfaces. High-pressure water sprays removed the loosened scale. After leaving the scale breaker, the slab enters a set of pinch rolls, which are separately motor driven and which direct it into the four-high mill stand. The 3-in. slabs are given approximately five flatting passes and the 4-in. slabs approximately eleven flatting passes back and forth through the mill, while resting on the roller tables, which are spanned by the hot coiling furnaces. During subsequent passes a set of dogs guides the strip into either of the hot coiling furnaces. The hot coiling furnaces are gas-fired and maintain the strip at rolling temperature throughout its length.

When the rear end of the strip emerges from the mill and is still in the grip of either of the pinch rolls, which are located between each of the hot coiling furnaces and the mill stand, the mill is reversed and the strip returns through the work rolls and the pinch rolls and into the opposite hot coil furnace, where it is again coiled and reheated to the rolling temperature. Reduction continues with the piece being coiled and uncoiled until it is rolled nearly to the desired gage. Following this, the strip, instead of being entered into the coiling furnace after the final pass, is conveyed by a roller table to a cold coiler, where the strip is wound into a finished coil.

Strips have been rolled by this method to approximately 12 and 14 gage and up to 36 in. in width. The maximum rolling speed possible on the experimental mill is about 300 fpm, at which speed 4-in.-thick slabs 9 ft long were converted into strips of about 12 gage in 6 to 6½ min.

The experimental rollings have given good indications as to the commercial possibilities of this type of mill. Increased rolling speeds are possible that, if applied to an actual mill installation, would enable one stand to produce an estimated tonnage of approximately 12,000 tons per month of 36-in.-wide 12-gage strip. While no edging rolls are used on the experimental mill, they are contemplated in the design of any future mill in order to roll more exactly the desired width of product and assist in breaking up the initial furnace scale. The demonstrations have further indicated that a very satisfactory hot-rolled product is possible.

Further development in the modernization of hand-operated sheet and tin mills has continued during the year. Many hand mills have been equipped with automatic mechanical feeders and catchers in arrangements known as the "combination system" or "combination method." These have resulted in increasing the production of the old type of tin and sheet mills to approximately one and one-half and three times their respective original outputs, with savings in labor up to about $5 per ton, together with better quality of product, a higher percentage of prime material, lower scrap loss, and the elimination of hard manual labor.

Electric-Weld Pressure Pipe

The use of electric current for welding purposes has extended into a variety of fields previously dominated by other methods. However, the following remarks are confined almost exclusively to the use of electric current for the manufacture of electric-welded pressure pipe. While mechanical, bedstead, and other small-diameter light wall tubing of a similar nature has been successfully produced by the electric-weld process for a number of years, it is only within the last few years that commercial pressure pipe has been manufactured by this method. The pressure-pipe demand up to the time of the entrance of the electric-weld process had been served by the butt-and-lap-weld and the seamless-hot-process systems, with the lap-weld method gradually disappearing from the picture. The invasion of the pressure-pipe field by the electric-weld process was first directed against line pipe and kindred products, and a number of large and successful installations had been made in various parts of the country of line pipe manufactured by the electric-weld process. Quite recently successful attempts have been made to enter the casing and similar pipe fields, which in recent years had been almost exclusively supplied by the seamless method of pressure-pipe manufacture. There are several different methods employed today in the manufacture of electric-welded pressure pipe, and there probably will be other methods developed, as the process, in the main, is in its infancy, and a great amount of thought is being given the problem, as it apparently offers an opportunity for reducing the costs of manufacture of pressure pipe in a rather wide range of pipe sizes, which is naturally attractive to the pipe manufacturer. Prominent among the methods employed today in the manufacture of electric-welded pressure pipe are, first, the arc method, in which a foreign metal is deposited between the edges of the shaped skelp to form the weld; second, the momentary flash method, in which the slightly separated edges of the formed blank are heated by establishing an arc between them that is maintained for a short period and then forcing the edges together to form the weld, the current being supplied to the work either by induction or by means of elec-

trodes; third, the continuous induction flash method, in which the formed blank is fed continuously forward, with the edges separated, to the welding zone, where the edges are gradually brought together and a continuous short arc is maintained by means of an induced electric current in the pipe blank; fourth, the resistance method, in which the formed blank is fed continuously forward, with the edges separated, to the welding zone, where the edges are gradually brought together and current is allowed to flow across the joint, the current being supplied to the work by means of electrodes and not of sufficient voltage to establish an arc. Line pipe within a certain range of sizes can be produced by any one of these methods at present. The resistance method of electric welding is demonstrating that it is also suitable for the manufacture of casing and similar products, and it is quite possible that the field of some of the other methods may be extended in the future.

The successful manufacture of electric-welded pressure pipe is not dependent alone upon the welding process, as there are a number of other operations that the skelp must go through before being delivered to the welder that are of great importance, such as the preparation of the edges of the skelp, the cleaning of the surfaces of the skelp, and the forming of the blank. The forming of the blank is a particularly difficult operation, and the success obtained at the welder is largely dependent upon this operation. The process of producing acceptable electric-welded pressure pipe is more of a mechanical than an electrical problem, and the actual welding is materially simplified if a properly prepared formed blank is supplied the welder.

Some of the advantages of electric-weld pressure pipe over seamless in particular are, first, lower production costs above $3^1/_2$-in.-outer diameter; second, larger sizes can be produced; third, uniform wall thickness; fourth, ability to produce longer lengths; fifth, more adaptable to the higher carbon and thinner wall piping that appears to be the trend of the trade today.

It is possible with the resistance electric-welded methods, by the employment of only one welder, to produce more than 10 miles of pipe in a 24-hour day. Due to stagnant business conditions, less advancement has been made in the manufacture of electric-weld pressure pipe than would otherwise have been accomplished had conditions been normal, but sufficient progress has been made so that it can be definitely stated that the electric-weld method of pressure-pipe manufacture is here to stay and that in all probability it will decidedly improve its position in the near future.

Refractories

In considering the recent progress made in the field of refractories, attention is drawn to a number of types of brick that have been developed and to modifications that have been made to existing types in order to meet certain definite service requirements in the operation of industrial furnaces.

Included among these are high-alumina brick, those in which the mineral mullite has been developed to a considerably greater extent than in first-quality fire-clay brick, modifications in chrome and magnesite brick, kaolin brick, and special refractories—for example, silicon carbide and fused alumina.

The high-alumina brick type of refractories includes commercial brands containing approximately 50, 60, 70, and 80 per cent alumina. For certain applications they possess very definite advantages over first-quality fire-clay brick that may be stated as follows:

(*a*) They are more refractory, and the refractoriness increases with increased alumina content

(*b*) They offer greater resistance to the erosive action of certain types of slag

(*c*) They do not vitrify at as low temperatures as do first-quality fire-clay brick; this is important, since it results in a lower spalling tendency over high temperature ranges

(*d*) They possess greater strength at high temperature ranges.

High-alumina refractories find some important applications in the steel industry in blast-furnace stoves, in open-hearth checkers, and in water-cooled ports. In many plants in the steam-power field they are standard for the side walls and bridge walls of boiler settings where certain types of slag are to be resisted that more readily react chemically with first-quality fire-clay brick. The alkaline ash from oil fuel is very destructive to fire-clay brick at the extremely high operating temperatures that are commonly employed. High-alumina brick are therefore also used in the settings of high-temperature cracking units in the oil-refining industry. Another economical application for high-alumina brick is found in the glass industry, where they are used in the ports and checkers of glass tanks. Still another application is in the field of non-ferrous metallurgy—for example, in lead softening and refining furnaces. To a very large extent high-alumina brick have supplanted fire-clay brick in the burning zones of rotary kilns used for burning cement, lime, and dolomite.

The mineral mullite has a definite crystalline form. In the pure state it consists of 71.8 per cent alumina and 28.2 per cent silica. A certain amount of mullite is present in hard-burned fire-clay refractories, but the amount is more pronounced in refractories of the high-alumina type. Refractories with an especially high amount of developed mullite are particularly suited for glass tank flux blocks.

Progress has been made in the development of chrome brick of low spalling tendency and greater strength at high temperature. This is of particular value in connection with their use in the open-hearth steel furnace and in various furnaces used in non-ferrous metallurgy.

Magnesite brick of low iron content are finding favor for special applications, particularly where they are exposed to direct heat action. They are becoming used in furnaces employed in the metallurgy of copper and other non-ferrous metals.

Brick made from the high-grade kaolin may be considered as an intermediate between first-quality fire-clay brick and high-alumina brick. They must be burned very hard in order to reduce the residual shrinkage to a minimum.

There has been a wider use of special refractories, such as silicon carbide and fused alumina.

There has been a more general use of high-temperature bonding mortars in all types of refractory construction. Research has helped considerably in the selection of these materials for specific service conditions.

Plastic ramming mixtures have been developed and satisfactorily applied—for example, plastic (thermolith) chrome batch for bottoms in heating furnaces and in slag-tap boiler settings.

In general, the power press has been applied to the manufacture of practically all the various types of refractories, resulting in greater uniformity in size and texture of the product. Continuous tunnel kilns have taken the place of periodic kilns in many plants. However, because of their greater flexibility as to production and degree of firing, periodic kilns are not likely to be entirely replaced.

Steam and Power Generation

During the last year there have been no outstanding developments in blast-furnace and steel-plant steam-power installations, but there has been a constant tendency toward applying the policies inaugurated in recent years.

The trend continues toward greater centralization of steam and power production in units of larger size and greater efficiency,

toward higher steam pressures and more efficient heat cycles, and toward more careful control of combustion.

Boilers. Water walls are becoming more and more popular, due to the immense amount of radiant heat that they are capable of absorbing and the protection that they offer to the refractories in the setting. At least one boiler company is offering a complete steam-generating unit, including boiler, water walls, economizer, and air preheater, conveniently arranged for assembly on a single foundation.

Recent changes in the boiler code now permit welded boiler drums, with the result that riveted drums will probably soon become a thing of the past. Now that suitable X-ray apparatus for testing is available and the art of welding is well understood, there should be no cause for failure of welds when the work is properly executed and thoroughly inspected. The use of welded joints properly annealed should reduce, if not eliminate, the danger from embrittlement by caustic that is always present where riveted construction is used.

The trade has offered one or two new devices for use in connection with superheaters in the past year, such as means for controlling the volume of hot gases passing through the superheater and the design of a superheater suitable for small horizontal return-tubular boilers.

The use of more thoroughly cleaned blast-furnace gas made possible through recent developments in the art of electrical precipitation has been tried out in at least one plant during the past year, with the result that more complete combustion of the gas has been obtained and the boiler outages have been reduced from one cleaning and inspection every 30 days to one every 90 days. The efficiency of the boiler, economizer, and air preheater is also improved due to cleaner heat-absorbing surfaces.

Prime Movers. Further improvement in the efficiency of turbines has been made by refinements in design and the use of heat- and erosion-resistant alloys in the blades. The turbine manufacturers have been very diligent in adapting their designs and in utilizing materials suitable for higher temperatures and pressures, with the result that the upper temperature limits have been increased to approximately 1000 F.

The Morgoil Roll-Neck Bearing

By F. P. DAHLSTROM,[1] WORCESTER, MASS.

For several years a need has existed in two-high hot rolling mills for a rugged, precision-type bearing having a capacity great enough to carry existing loads, and which could be installed in the limited space available, without reduction of neck strength. This paper reviews the experimental work with roller bearings which eventually led to the development of a unit-type oil-lubricated sleeve bearing. A brief review of pertinent laws of bearing design is included, together with their application to rolling-mill problems. Following a description of the Morgoil bearing, some results of field tests are included which show how successfully the bearing has met the conditions imposed upon it.

THE Morgoil bearing was especially designed for application to the necks of steel-mill rolls. It embodies a type of construction in which the bearing assembly is removable as a complete bearing unit. The roll neck itself is not used as the journal, but fits into a sleeve contained in the bearing unit. The outside of the sleeve is accurately ground cylindrical and forms the journal proper. Before describing the mechanical details of the bearing unit, mention will be made of some of the experiments first conducted with other types of high-quality precision bearings, which eventually led to the development of a bearing of similar precision, but having, among other advantages, greater capacity in the limited space available.

Early Roller-Bearing Applications

Roller bearings of various types had been installed in merchant mills, both in Europe and the United States. The roll speeds were comparatively slow, which favored the introduction of a roller bearing, as such a bearing has its greatest capacity at low speeds. In these installations the roll bodies were long and grooved with comparatively deep passes. The rolling pressures therefore could not be higher than the breaking strength of these relatively weak rolls. Lubrication of the roller bearing was also more simple at these lower speeds, as a grease was quite suitable for the purpose.

Problems and Experiences in Attempt to Equip Strip Mills With Roller Bearings

In modern two-high strip mills the length of the rolls is deliberately made short so as to permit carrying extremely high rolling pressures without roll breakage. The ordinary open-type plain roll-neck bearing then remained as the limiting factor in two-high strip-mill rolling. As reliable performance of the roller type of anti-friction bearing in many industrial applications was a demonstrated fact, attempts were made by our company to use roller bearings in solving the two-high strip-mill roll-neck problem, but it was soon apparent that there were several inherent disadvantages.

At the outset it was necessary to use a smaller diameter roll neck in order to provide room for a bearing of suitable capacity. The usual roll-neck diameter is two-thirds the nominal roll diameter, and in order to install a roller bearing, the neck diameter had to be decreased about 20 per cent, which reduced the strength of the standard roll neck about 50 per cent.

The speeds of the finishing stands of strip mills are high; on the smaller sizes as much as 1000 rpm. As the effective capacity of a roller bearing decreases with increase in speed, the best that could be secured, even with the reduced neck size, was a bearing having a capacity barely great enough to carry the expected rolling loads. For the finishing stands of the larger size of strip mills, no roller bearings were submitted which could be guaranteed to successfully carry the expected loads continuously, and the only apparent solution was to install a larger mill and thus provide the necessary room for roller bearings of a suitable capacity.

Experimental work with roller bearings was therefore started on the smallest size of strip mill, and the first installation was made in the field. The power savings were, as anticipated, about 50 per cent. The mill roller, having a more efficient mill at his disposal, took heavier reductions, and the bearings soon failed, possibly because of overload or because of faulty lubrication. It was a question as to whether more installations should be made with bearings or necks that did not have inherently sufficient overload capacity.

The problem of lubrication also presented itself. In the installation referred to, grease was used as a lubricant, and after the bearing failure, the surface of the individual rolls had an appearance much like carbon. It is not known whether the excessive heat was caused by too much or too little lubricant, entrance of scale (with resultant binding), or inherent friction between rollers and retainers, etc., which might have been serious at heavy loads and high speeds.

In later designs it was decided to lubricate such high-speed bearings with oil. This method had the distinct advantage of being able to connect the bearings directly to the existing mill oil-circulating systems, the reliability of which systems had been well demonstrated. Many hours of shop testing showed that an ordinary oil was suitable for the expected normal loads, but it was soon found that the designs of closures which were recommended to retain grease at slow speeds were not satisfactory for retaining oil at high speeds.

From the foregoing, as well as other experiences, it was evident to us that in order to make a successful roll-neck-bearing installation with roller bearings, the following conditions must be met:

(*a*) First-class workmanship should enter into the manufacture of bearing enclosures and assembly of bearing parts, and the maintenance be assigned to responsible workmen

(*b*) The bearing must be kept free from foreign matter

(*c*) Thorough lubrication must be had at all times, as only the combination of cylindrical, or conical, surfaces of

[1] Engineer, Morgan Construction Company. The author entered the employ of the Morgan Construction Company in 1909 as machinist's helper, and from 1910 to 1913 was plant electrician. He was employed by the American Steel and Wire Company as electrician from 1913 to 1915 and from 1917 to 1919. During these periods he repaired and rebuilt steel-mill electrical equipment. In 1920 he entered the engineering department of the Morgan Company, and in January, 1931, was appointed research engineer, his duties being mainly experimental research and development of equipment.

Contributed by the Iron and Steel Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the rolls in contact with the bearing races approach anti-friction performance. (The friction between rolls and retainers and the friction between the ends of tapered rollers and the roller-confining means are serious limitations, especially at heavy loads and high speeds.)

(*d*) The bearing should not be loaded above its rated capacity.

After a consideration of these conditions, it was decided to investigate the possibilities of a flood-lubricated sleeve-type bearing made with comparable precision and given the same care that was demanded by the roller bearings.

Further Shop Experiments With Roller and Sleeve Bearings

A study of the modern theory of sleeve-bearing design indicated that this type had a greater potential capacity for our conditions than the roller type. This type of bearing could also be installed in existing mills without reduction of neck strength.

A pair of sleeve-type bearings were then made for a 10-in. strip roll, and the combination was installed in a standard housing. The other roll was equipped with roller bearings. The two rolls were then run tightly together with known pressures. Experiments were hardly begun when a neck on the latter roll broke at a bearing load of 42,000 lb at 500 rpm. A new roll of steel was then substituted so as to permit carrying the pressures desired. For a number of days, test runs were made in which the pressures, powers, speeds, oil flow, bearing, and room temperatures, and rise of temperature in the circulating oil were measured. The data in Table 1 are compiled from these tests.

TABLE 1 DATA OBTAINED FROM TEST RUNS, 10-IN. STRIP HOUSING

(Upper roll fitted with sleeve bearings; lower roll fitted with roller bearings)

Rpm	Bearing pressure	Hp[a]	Oil temperatures Inlet, deg F	Oil temperatures Outlet, deg F	Oil circulation, qt. per min. per bearing Sleeve	Oil circulation, qt. per min. per bearing Roller	Remarks
400	10,000	13	...	...	..	..	Broke cast-iron neck; roller bearing mounted; replaced with steel roll

[a] Includes all bearing losses and rolling friction of mill rolls.

The limit of rolling pressure which could be applied was determined by the strength of the standard size neck on the sleeve bearing. Eventually this pressure was deliberately exceeded, and the neck broke at a load of 73,000 lb at 50 rpm. No damage whatsoever occurred to the bearings.[2]

Fig. 12 shows the broken roll ends. The roll at the right was carried on roller bearings. The disk on the extreme right was cut from the neck which broke at a load of 42,000 lb at 500 rpm. In order to determine the effect of roll speed, the opposite neck was broken in a testing machine, with the bearing mounted in place and with the test load applied to the same point on the bearing enclosure. The neck broke at a static load of 81,000 lb. The fractures at both ends appeared to be similar and the Brinell hardnesses were alike. The calculated neck stress was 22,300 lb per sq in. If the results of further tests were similar to this, we would infer that the effective capacity of a roll neck at 500 rpm would be one-half its static capacity.[3]

The roll at the left fitted the Morgoil bearing and broke at a static load of 158,000 lb. The corresponding neck stress was 25,500 lb per sq in. The opposite end of the roll broke at an applied load of 73,000 lb at 50 rpm, or only 46 per cent of its static capacity. (This should have been higher. The steel roll was badly spalled, however, and severe vibrations were felt in the housing during the run, which probably imposed additional loads on the bearings.)

Our experiments proved conclusively the reliability of the flood-lubricated bearing for this application. It showed that the bearing is really anti-friction, the low frictional losses being in close agreement with calculations.

Some Laws of Sleeve-Bearing Design

A—Intermittently Lubricated Sleeve Bearings. In several handbooks and publications on bearings there may be found the formula pv = a constant, in which p is the bearing pressure in pounds per square inch of projected area and v the surface speed of the journal in feet per minute. The constant was originally 60,000, and in some designs, according to the literature, was as high as 200,000.

If we trace the origin of this formula we find that it was introduced by Dr. Thurston, first president of The American Society of Mechanical Engineers, and the constant he recommended was based upon observations he had made of the "behavior of the journals of the engines of naval steamers in 1862." This formula is used in proportioning the lengths of bearings in mills constructed by our company where such bearings have their oil supply regulated by the ordinary "sight-feed" oiler.

If this formula is used to determine the length of a roll neck 7 in. in diameter on a 10-in. strip roll rotating at 1000 rpm and carrying a rolling load of 50,000 lb, it will be found that its length should be 33 in., instead of the usual dimension, 9 in. The example cited is typical, and one should therefore expect the ordinary open, plain roll-neck bearing to have the short life that it does. If water were not continuously and copiously used, the bearing would promptly melt.

B—Flood Lubricated Sleeve Bearings. When a bearing is continuously lubricated with a suitable oil, the conditions are entirely changed. The laws of hydrodynamic theory of lubrication then apply. One of the early recorded references on the subject of flood lubricated bearings is the paper by Reynolds (1).[4] In the reports and papers presented by the A.S.M.E. Special Research Committee on Lubrication, there may be found a wealth of information and references on this subject. Among those who have presented papers of great value to us in the development of the Morgoil bearing are Kingsbury, Howarth, McKee, Karelitz, Bradford, and Hersey.

Although many discussions have been presented explaining the phenomena of complete lubrication of journal and bearing, perhaps the author's interpretation of this subject will be in

[2] A special gage was developed by the author for measuring rolling pressures. It consisted essentially of a sheet manganin resistor, insulated with sheet mica and placed between steel blocks. These blocks were mounted in a suitable enclosure, and the combination was inserted between the roll-adjusting screw and bearing chock. The resistor formed one arm of a Wheatstone bridge. The resistance of manganin changes proportionally with pressure; therefore the change in resistance of the gage unit, caused by rolling pressure, was measured by a galvanometer graduated to read the rolling pressure directly in pounds.

[3] It is interesting to note in a catalog of a prominent roller-bearing company that the rated capacity of the bearings at 500 rpm is 40 per cent of the static capacity. In the author's opinion the percentages of static capacity at various speeds, as established by the roller-bearing manufacturers, might well be used as a starting point in estimating the variation of roll-neck capacity with speed.

[4] Numbers in parentheses apply to similarly numbered items in the List of References given at the end of the paper.

order at this time, after which the resulting formulas will be applied to the design of roll-neck bearings.

When a bearing is continuously supplied with a sufficient quantity of oil, it appears that the adhesion of the oil to the rotating journal causes the journal to function as a remarkably effective and efficient pump. The journal pulls some of the oil through the region of minimum clearance. The oil which is not drawn through this region must escape at the ends of the bearing. It requires a tremendous squeezing force to do this, and the resulting pressure actually lifts the journal away from the bearing, permitting the oil to separate the two by a film of definite thickness, which can now be fairly accurately calculated (3).

The more viscous the oil, the more pressure will be required to force the oil out at the ends; hence we have a first law of flood-lubricated bearings as follows:

The carrying capacity is proportional to the viscosity, Z, of the oil.[5]

As the speed of the rotating journal is increased, the journal draws in more oil (the average velocity of the oil being about one-half the surface velocity of the journal); consequently, a proportionately greater force is required to squeeze the oil out at the ends of the bearing. From this fact we have a second law for flood lubricated bearings:

The capacity is proportional to the speed of the journal.

For a given speed it is obvious that the amount of oil carried in by the journal is substantially proportional to the axial length of the bearing, thus we have a third law:

The capacity is proportional to the axial length, L, of the bearing.

We can combine these laws into an expression as follows:

$$\text{The bearing capacity in lb } P = \frac{Z \times \text{fpm} \times L}{\text{a number}} \quad \ldots\ldots [1]$$

If p = the bearing pressure in lb per sq in.; D, the journal diameter in in.; N, the rpm, then:

$$P = pDL \quad \ldots\ldots [2]$$

and

$$\text{Fpm} = \frac{ND \times 3.14}{12} \quad \ldots\ldots [3]$$

Substituting these values in Equation [1], we have:

$$pDL = \frac{Z \times ND \times 3.14 \times L}{\text{a number} \times 12} \quad \ldots\ldots [4]$$

or

$$p = \frac{Z \times N \times D \times 3.14 \times L}{12 \times DL \times \text{a number}} = \frac{ZN}{\text{a number}} \quad \ldots\ldots [5]$$

From the foregoing we derive that the load-carrying capacity of a given bearing in lb per sq in. is equal to the viscosity of the oil times the rpm of the journal divided by a number that is established by experience.

The minimum value which this number can have, without rupture of the oil film, depends upon the clearance ratio and the accuracy of finish, as well as the condition of the journal and bearing surfaces. With clearances of from 0.001 to 0.00125 in. per inch of journal diameter and with a high degree of accuracy, McKee (5) has found by experiment that this number can be as low as 5 before failure of the oil film begins.

The experimental work of McKee was conducted with bearings 2 in. in diameter. The author, in connection with the development of the Morgoil bearing, has consistently found that at low speeds and with bearings 8 in. and 11 in. in diameter, this number can be as small as $1^1/_2$ and 1. In practice a value of from 10 to 25 times this may be advisable in order to have a conservative design.

Transposing Equation [5], we obtain

$$\text{Number} = \frac{ZN}{p}$$

The use of the variable ZN/p in formulating laws of lubrication of sleeve-type bearings was first proposed by Hersey. (2) He showed that under certain assumptions the coefficient of friction and relative film thickness was a function of this variable; also that the carrying power or safety factor of a bearing might be defined from its relative film thickness.

In papers by Howarth (4) and Karelitz (3) the expression ZN/p is one of the factors which determines the eccentric position of a rotating journal in its bearing. Karelitz still further proposes that the minimum oil-film thickness (which is easily found when the eccentric position of the journal is known) might well be used in determining the safe carrying capacity of a bearing.

Earlier in this paper it was shown that by the Thurston formula, the length of a roll-neck bearing 7 in. in diameter for a 10-in. strip mill carrying a load of 25,000 lb should be 33 in., instead of the conventional length of, say, 8 in.

We will now calculate the capacity of a bearing 7 in. in diameter by 8 in. long, by the ZN/p method, in order to determine the suitability of a continuously lubricated bearing for this application.

The viscosity Z of the oil in the circulating system will be about 150 centipoises (750 sec Saybolt), and a close approximation at the temperature of the oil film will be 50 centipoises. If a value of 20 for the characteristic number of the bearing is chosen (which from our experience is conservative and would be considered as a reasonable one), we obtain a value of the permissible load in lb per sq in. of:

$$p = \frac{ZN}{20} = \frac{50 \times 1000}{20} = 2500 \text{ lb}$$

The load on each bearing being 25,000 lb, the total projected area should be 25,000/2500, or 10 sq in. The projected area of a bearing 7 in. in diameter by 8 in. long is over five times this amount, which means that the bearing has a factor of safety of over 5. The capacity of such a bearing is therefore far above the breaking strength of any chilled cast-iron or alloy cast-iron roll manufactured today.

To express the capacity of the bearing in another way: With a characteristic number of 20, the bearing could easily carry the full rolling load at speeds as low as 200 rpm.

For a condition considerably different, let us determine the safe carrying capacity of a bearing for a neck of an 18-in. roll at 50 rpm. Such a bearing would have a projected area of 200 sq in., and the viscosity of the oil film would be about 350 centipoises. The characteristic number at this slower speed can well be taken at 10. The bearing will have a safe capacity of $200 \times (ZN/10) = 200 \times (350 \times 50/10) = 350{,}000$ lb. This is equal to the safe carrying capacity of a neck having a diameter of two-thirds the roll diameter, or 12 in.

The coefficient of friction of a flood-lubricated bearing having a clearance ratio of 0.0015 is approximately $0.001 + (0.00004 \times ZN/p)$.

[5] Viscosity is usually specified in seconds Saybolt at 100 F. The seconds Saybolt viscosity is the actual number of seconds required for a standard amount of oil to drain from a calibrated vessel; hence the larger this value in seconds, the more viscous the oil. In bearing calculations the viscosity is denoted by the absolute viscosity in centipoises, which value is approximately one-fifth the Saybolt viscosity.

For the bearing of the 10-in. strip mill noted above, operating at a ZN/p value of 20, the coefficient of friction will be 0.001 + 0.0008 = 0.0018 and the frictional losses at 25,000-lb bearing load will be, per bearing:

$$\frac{25{,}000 \times 0.0018 \times 1000 \times 8 \times 3.14}{33{,}000 \times 12} = 2.85 \text{ hp}$$

or 11.4 hp per stand, which loss is very small when we realize that the losses in the ordinary type of open bearing would be over 20 times this amount.

The coefficient of friction of the bearing 14 in. in diameter for the 18-in. mill will be 0.001 + 0.0004 = 0.0014, and the frictional losses per stand will be:

$$\frac{4 \times 350{,}000 \times 0.0014 \times 50 \times 14 \times 3.14}{33{,}000 \times 12} = 10.9 \text{ hp}$$

which is also negligible, as the losses with the plain open-type bearing would be about 700 hp. In practice, Morgoil bearings run quite cool, as would be expected from these figures. No water is applied to the bearing enclosure, as the small amount of heat developed is readily carried away by the oil.

It has been mentioned that the minimum oil-film thickness might also be used as a criterion for safe bearing capacity. From the paper by Karelitz (3), the minimum oil-film thickness of the high-speed strip-mill bearing operating with a characteristic number (ZN/p) of 20 would be 0.0009 in., which is greater than his recommended conservative value of 0.0007 in. The corresponding film thickness of the 18-in.-mill roll-neck bearing would be, according to the method by Karelitz, 0.0005 in., which we find from mill experience is safe.

A Condition Not Covered by Theory

From the foregoing it is apparent that the rotating journal in a properly designed bearing is at all times separated from the bearing by an oil film of appreciable thickness. No wear takes place. The only friction involved is fluid friction, which is non-destructive, the important effect being to raise the temperature of the oil. As the speed of the rotating journal is reduced, the oil film becomes thinner, and at very slow speeds the film will not be continuous and the coefficient of friction of the bearing will suddenly increase. The actual speed at which this breakdown of the oil film starts to occur is low and will depend upon the accuracy and finish of the journal and bearing. (At a unit bearing load of 3000 lb per sq in. and with a plain mineral oil we have been able to run as low as 1 rpm without disrupting the oil film. The amount of wear which will take place when the journal operates below this critical speed or when the journal is started or stopped will likewise depend upon the accuracy of finish of the parts, also upon the degree of polish of the journal. Fortunately, in hot rolling the bearing starts and stops under practically no load, and the wear in this region is negligible.

Description of Bearing

In considering the design of a suitable sleeve bearing it seemed best not to use the roll neck for the journal, but to provide a sleeve of high-quality steel which would fit on the neck. The outside of the sleeve could then be ground and polished to obtain the most suitable journal surface. This basic arrangement was adopted, and the combination was called the Morgoil roll-neck bearing to distinguish it from any different construction that had been or might be developed.

Fig. 1 shows a cross-section of the working-side top roll bearing mounted in running position on the roll, and Fig. 2 shows the bearing at the drive side. The roll necks are made tapered to permit easy removal or replacement of the bearing units. In Fig. 1, A is the sleeve, B the thrust-bearing ring, and C a locking nut. The sleeve is prevented from creeping by a key, which key also serves to prevent relative rotation of the thrust ring. The locking nut C secures the thrust ring and sleeve in place on the roll neck, and as all of these parts therefore revolve with the roll, they are cross-sectioned in the same general direction. The casing D contains a replaceable bearing liner E which is made of either steel or bronze and has on its inner surface a high-grade babbitt centrifugally cast in place.

The sleeve, and therefore the roll, are held in a fixed endwise position by the two stationary babbitt-faced thrust rings F. A threaded ring G is used to adjust the thrust plates. One-half of the outside surface of the ring is notched, and the thrust bearing is easily adjusted by first screwing up the ring G tightly and then backing it off a few notches.

The oil for the main bearing enters the casing at hole H, after which it travels through the passages indicated by dotted lines and enters the bearing liner at holes J. Pressure relief and drain grooves are provided at the roll end of the bearing liner as shown. These grooves effectively drain the oil from the liner. Oil slingers are provided on the steel sleeve, which in combination with the grooves prevents any escape of oil without the use of auxiliary packing rings. The drained oil is free to flow through the passages at the bottom of the casing, from which it enters a drain pipe, not shown.

In order to prevent water and scale from entering the bearing, the casing is grooved for a circular ring K, which is made of bakelite impregnated material or its equivalent. The ring is backed by springs which force the ring against the end of the roll body and thus effectively prevent the entrance of water. Such a solid ring appears to be much superior to split rings or resilient packing, which had been used with more or less success in connection with our earlier experiments. By using the end of the roll for a sealing surface instead of the neck, the need for split rings, etc., was avoided.

The arrangement in Fig. 1 shows one method of lubricating the thrust bearing. Where there is no need of the neck projecting through the bearing, there is provided an entering pipe in the center of the enclosing cover. A bakelite washer, backed by a spring, prevents wastage of oil and causes it to be delivered into the space K with line pressure, from which space the oil is conveyed by drilled passages directly to the thrust bearing as shown. Where the neck must project through the bearing at the working side of the mill, the lubricant for the thrust bearing is supplied from the same passages as supply the main bearing.

In Fig. 2, which shows the bearing for the drive side of the mill, the end adjacent to the roll is exactly like the corresponding end of the bearing in Fig. 1. The bearing sleeve A is free to float endwise in the bearing liner E. In strip mills the casing D is held endwise by lugs or the equivalent which fasten to the roll housing. In mills having rolls with grooved passes the two casings are connected by means of spacer pipes and tie rods, as shown in Fig. 3. In both types of mills the endwise adjustment of the roll is made entirely at the working side of the mill by means of lugs on the casing shown in Fig. 1, which cooperate with adjusting nuts and studs on the housing.

The bearing in Fig. 1 is readily removable as a unit by first removing the end plate and next unscrewing nut C. A puller is then applied, and after tightening the puller screw the end is struck a hammer blow, which frees the sleeve from the neck. The entire unit may then be withdrawn. The adjustment of the thrust bearing is not affected.

For the bearing in Fig. 2 it is only necessary to remove nut C and the split threaded ring which engages with the nut before applying the puller. The easy removal of the bearing unit is thus seen to be a very important advantage of the Morgoil

type of construction. Due to a special method of lubricating the inner side of the sleeve, it is not necessary to force the unit tightly on the roll neck, and its removal is often easily accomplished without the puller fixture.

In replacing the bearing, further advantages of this construction are apparent. If, when the bearing is partly slid on the tapered portion of the neck, it is advisable to lower the bearing a fraction of an inch by the crane, no harm whatsoever can be done to the bearing or its running surfaces in case the crane operator misunderstands the signal and either lowers the bearing too much or even moves it in a direction opposite to the one signalled.

In order that the necks and bearing sleeves of all units may be strictly interchangeable a set of standards was made and an accurate system of gaging was established. Fig. 4 shows part of a roll with two gage rings on the neck. The distance between the two rings checks the amount of taper. A feeler gage *A* having a plus and minus tolerance is used to measure the distance between the rings. The errors in taper magnify the corresponding errors in the space between the rings about five times, therefore the system is very sensitive. Once the correct taper is established, the neck diameter can be reduced to the desired size, at which time a second gage *B* having a plus and minus tolerance can be inserted between the larger ring and the end of the roll. The tolerance on this gage is comparatively large, as the bearings are made with ample end clearances.

In order that the barrels of the rolls may be readily ground or turned with the standard roll shop equipment, auxiliary cylindrical sleeves are provided having a tapered bore to fit the roll neck. It was first thought necessary to force the sleeves of the bearing unit on to the neck very tightly as no key was provided to prevent relative rotation between the two. With moderate rolling pressures no "creep" occurred, but with heavy pressures it did occur, and scores and grooves were made in both neck and sleeve. Attempts were made to measure this rotational force which caused the creep. Keys of successively larger size, from $^1/_4$ in. up to $^3/_4$ in. (in a 14-in. roll bearing) were tried. Most of them sheared. In order to demonstrate the creeping force, a simple experiment was made which pointed out a remedy.

A belt was placed on a wood cylinder (see Fig. 5). One end was held by the finger, the other end being free; a roller was then pressed against the belt and rolled toward the finger. Due to the temporary elongation of the belt under the roller a "creep" of the belt resulted in the direction of the arrow *A*, which caused the belt to bulge as shown in Fig. 5. As the belt was comparatively stiff, an appreciable resisting force was required at the finger tip in order to prevent the belt from slipping forward at that point. As the roll advanced toward the finger, the belt had to flatten; consequently, the finger would have to yield or else the belt would have to slip backward in the direction of the arrow *B*. It was evident that if a lubricant were applied between the belt and the cylinder, the belt would slip back easily; consequently, only a small force would be required at the finger tip to prevent the belt from creeping forward.

Fig. 6 shows the parts of the sleeve, key, oil film, and bearing as represented by the parts in Fig. 5. The bearing pressure is transmitted through the oil film (Fig. 6), which pressure is represented by the roller in Fig. 5. This compresses the sleeve slightly, and because of rotation there is a tendency to creep. Several holes were drilled radially in the sleeve, allowing the oil-film pressure to force oil through the holes and thus lubricate the surface of the sleeve and roll neck. The force of creep could not build up above the frictional resistance between the sleeve and neck, and as this was now greatly reduced, it was found that a $^1/_4$-in. key was not sheared even under the heaviest loads obtainable in our experiments.

It is now our practice to tighten the retaining nut *C* (Figs. 2 and 3) a moderate amount, which permits the lubricant to do its work and preserve the tapered surface, and, as before mentioned, the removal of the bearing unit is often accomplished without the use of the standard puller fixture.

Fig. 7 is a photograph of a 10-in. roll. It will be noticed that the neck diameter where it joins the roll is large (about seven-tenths the nominal roll diameter) and that the fillet has a large radius. Fig. 8 shows a 10-in. roll with bearing units mounted in place on the roll. Fig. 9 shows a bearing installation made in an existing 18-in. open-top housing.

Results of Field Experience

Pressure and power readings were taken on the finishing stand of a 14-in. strip mill in which the life of the ordinary plain open-type neck bearing was very short. The highest rolling pressures and electrical loads were obtained when finishing 6 in. by 0.038 in., with a reduction of 10 per cent, as will be seen in Table 2. The wear of the bearing under these conditions was such that roll adjustments were necessary after each bar was rolled.

TABLE 2 DATA OBTAINED FROM TEST RUNS, 14-IN. STAND, PLAIN BEARINGS

Item	Finishing size, in.	Per cent reduction	Amperes at 600 volts	Rolling pressure	Delivery speed, ft per min.	Approx. temp., deg F
A.....	$9^1/_2 \times 0.062$	6	1000	180,000	1150	1400
B.....	11×0.105	7	1000	191,000	1150	1500
C.....	6×0.038	10	1350	210,000	1750	1300

At the time the tests were made there were, to our knowledge, no bearings of any type which could be made to fit in this housing and which could be guaranteed to carry the maximum rolling load (210,000 lb) continuously at a speed of 480 rpm.

The first set of 14-in. Morgoil bearings were then made and installed in this stand for test. They were designed to carry a rolling load 50 per cent in excess of the maximum measured. The neck stress under these conditions would be as high as good practice would permit—12,000 lb per sq in. The bearings performed in every way as expected. During this test the bearing casings were only comfortably warm to the hand and the only cooling water used was on the roll barrel proper.

Heavier reductions were taken with less power consumption, as will be evident by comparing items A and B in Table 3 with similar items in Table 2. It will be seen that reductions 50 per cent higher were carried which resulted in a 35 per cent increase in rolling pressure. The power consumption, however, was from 40 to 50 per cent less. A study of several readings showed that the power saving for given reductions, etc. was 70 per cent. This is more than can be reasonably expected for an entire strip mill. A fair value would be 50 per cent.

TABLE 3 DATA FROM TESTS 14-IN. STAND, MORGOIL BEARINGS

Item	Finishing size, in.	Per cent reduction	Amperes at 600 volts	Rolling pressure	Delivery speed, ft per min	Approx. temp., deg F
A.....	11×0.062	9	425	242,000	1270	1400
B.....	11×0.105	11	600	265,000	1250	1500
C.....	....	..	700	300,000	....	....
D.....	....	..	800	[a]	....	....

[a] Roll broke at load estimated at 340,000 lb as current was 800 amp.

The data for item C were taken when a few bars, colder than normal, were rolled. As will be seen from Table 3, one of the rolls finally broke. The electrical load was 800 amp, according to a recording ammeter in the motor circuit. No pressure gages were in the stand when the breakage occurred, but as the rolling pressure and electrical load were substantially proportional, a fair estimate of the rolling pressure at the time would be 340,000 lb.

A second piece passed through the rolls before the break

was noticed, but owing to the low frictional resistance of the bearing, the two half-rolls held together and no outward sign of bearing distress was evident. The bearings were later examined and found to be in perfect condition. Fig. 10 is a photograph of the broken roll. The roll was a sound one with a normal depth of chill. Fig. 11 is an unretouched photograph of one of the bearing liners which was installed with the roll in Fig. 10. The photograph was taken after the roll broke and shows the perfect condition of the liner; in fact, the bearings were not even "run in." The dark areas in the center are high spots. This condition is typical of all the other bearings.

As a further example of the stamina of this design of bearing, an 18-in. roll (in the housing shown in Fig. 9) was broken when carrying an estimated load of 1,000,000 lb, with no damage to the bearings. The normal maximum load on this stand is approximately 800,000 lb and occurs when rolling a 22-in. slab from 2 in. to 1 in. in thickness.

Power Savings

The power savings possible with flood-lubricated bearings are very high. In the finishing stand of a strip mill the savings, as noted, have been as high as 70 per cent. This is probably the maximum. A fair average for the rolling-mill industry would be approximately 40 per cent.

The coefficients of bearing friction in billet and sheet bar mills and in the roughing stands of merchant and rod mills have been measured by us and found to vary from 5 to 20 per cent. A fair average would be 10 per cent, which is 25 times the coefficient of friction of a flood-lubricated bearing installed in mills of this type. This means that practically all (24/25) of the power lost in roll-neck friction can be saved by the use of flood-lubricated bearings. The percentage of the total power consumed in bearing friction in such mills probably varies from 30 to 50 per cent, and both the roller and flood-lubricated bearing will save practically all of this wasted power.

In high-speed stands the coefficient of friction of a flood-lubricated bearing operating at a ZN/p of, say, 100, is one-half of 1 per cent, while the average coefficient of friction with the open-type plain bearing is about 5 per cent. The flood-lubricated bearing will therefore save nine-tenths of the power lost in friction. This will be at least 50 per cent of the total in strip mills and about 30 per cent in rod mills.

Lubricants

Any lubricant used continuously in a steel mill sooner or later becomes contaminated with water from condensation, or it may at times enter directly. Iron oxide in the form of fine scale is always present, together with rust which forms on the inside of all steel enclosing parts.

A most desirable property of a steel-mill lubricant, therefore, is its ability to separate from water. So far as the author knows, the only lubricant that has this property is a highly refined mineral oil. Compounded oils and substances which may be added to such an oil may improve its lubricating properties (increase its oiliness, etc.), but the stability of the lubricant will then be destroyed and the resultant emulsions which may form cannot be tolerated. Even the best of straight mineral oils, which have the desired water-separating qualities when new, may undergo quite a decided change with use; therefore the problem of removing water is always an interesting one.

The flood-lubricated, sleeve-type bearing successfully carries heavy rolling pressures in the restricted space available, using as a lubricant straight mineral oils, which at the present time function best in circulating systems.

Conclusions

The Morgoil type of roll-neck bearing has a very high load capacity, generally far in excess of the roll-neck strength. The neck diameter at the point of maximum stress is about seven-tenths the nominal roll diameter.

The bearing can be removed easily from the roll neck as a unit without affecting any adjustments or exposing the bearing surfaces.

A straight mineral oil of proper viscosity is entirely suitable as a lubricant. Such an oil has the highest stability in the presence of water, which is not true of compounded oils or lubricants. This makes it possible to lubricate the bearings from existing circulating systems the reliability of which is well known.

Maximum power savings are obtained, as the bearing runs on an oil film of definite thickness.

There is no appreciable wear, the only roll adjustments required being due to pass wear.

The Morgoil roll-neck bearing was developed only after thorough investigation and experiments with other types of existing precision bearings had shown the need of such a construction. It has successfully met the severe conditions that are peculiar to metal rolling mills, and therefore has a definite place in this field.

Discussion

W. R. Clark.[6] The writer has long been interested in the development of reliable roll-neck bearings having low coefficients of friction. Pressures are encountered in the cold rolling of brass on 20-in.-diameter rolling mills with necks about 15 in. in diameter as high as 500,000 lb per roll neck at roll speeds of from 15 to 25 rpm. Some rough determinations of roll-neck friction for this type of rolling indicated that when a good grade of graphite grease was used on the roll necks, with plenty of cooling water, discharged directly on the neck itself, a coefficient of friction of 0.013 to 0.016 was obtained. Another rough test on an 18-in. roll, running at approximately 60 rpm, with a bearing diameter of approximately 13 in. and load per bearing of from 200,000 to 300,000 lb, indicated a coefficient of friction of from 0.05 to 0.06. These bearings obviously ran warmer than those having the lower speed and lower coefficient of friction.

In cold rolling thin-gage material it is well known by rollers that if the roll necks heat up, the gage of the material rolled is affected, due to the increase in diameter of the necks and the rolls near the necks, so that rolling to accurate gages made it necessary to limit the speed of rolls and the pressures between them to points where the bearing temperature could be maintained substantially constant.

Some years ago the writer went so far as to build a set of flood-oil-lubricated bearings for an 18-in. mill, but owing to inadequate methods of sealing and difficulties with taking end thrusts, these bearings were discarded. Since that time we have followed the

[6] General Works Manager, Bridgeport Brass Company, Bridgeport, Conn. Mem. A.S.M.E.

developments in anti-friction bearing design with the belief that sooner or later reliable bearings with low coefficients of friction would be available for two-high rolling mills.

Several years ago we discussed the matter with Mr. H. A. S. Howarth, and his company offered the design of a precision oil-film-lubricated bearing for a 12-in. rolling mill. Mr. Howarth convinced us at the time that it would be perfectly possible to design a satisfactory flood-lubricated bearing broadly of the type which Mr. Dahlstrom has described and that it should work successfully on a rolling mill, if proper oil were supplied and maintained at proper temperatures and if the seals were adequate to keep the bearing free from roll scale and cooling water.

There was another consideration involved, however, in the 12-in. mill, and that was the probability of starting the mill at times with the bearings preloaded. In cold rolling thin strip the pressures developed between the rolls may run anywhere from 30,000 to 100,000 lb per inch of width of the strip rolled. The elastic spring of a cold-rolling mill plus the elastic deformation of the rolls, due to bending and due to actual flattening at the line of contact with each other or with metal passing through them, may be two or three times greater than the thickness of the metal being rolled. In this case the reduction of gage in rolling is accomplished by the additional spring of the mill and rolls caused by entering the strip into the bite of the rolls, which have been already running together in elastic contact. The rolling-mill bearings therefore may be preloaded with no material in the rolls up to 75 or 80 per cent of the load which they carry while rolling.

If a mill, set up to roll thin-gage material, is shut down for any reason and started up again, it is likely that most of the oil will be squeezed out from between the bearings, and the first fraction of a revolution in starting such a mill might be made with a metal-to-metal contact of journal and bearing. This contact would continue until enough oil were drawn into the bearing to reestablish the normal oil film. Variation in the temperature of the body of a roll would have its effect on the temperature of the roll neck, which in turn would tend to change the oil-film clearance between the neck and its journal.

Roller bearings solved the particular problem of rolling in which we were interested on our 12-in. mills. These mills have been increased in speed from 60 to 120 rpm and carry loads up to 125,000 lb per bearing while rolling thin strip. The gage variation with roller bearings is less at the higher speed today than it formerly was at the lower speed with the old grease-lubricated plain bearing. The power consumption per ton of material rolled has been reduced 45 to 60 per cent.

The author, with his bearing, has gone a step beyond the field which may be served by roller bearings. He has developed a bearing which is suitable for heavy pressures at high speeds and at the same time one that can be built within the limits of a rolling-mill housing. It is well known that the carrying capacity of a roller bearing decreases as the revolutions per minute increase, and if the paper is read correctly, there are indications that the author's bearing works even better at high speeds than at low speeds.

He has described an excellently designed bearing and also has solved the problem of roll changing in a very nice way. The writer would like to have him discuss the question of starting up a mill with preloaded bearings and also the effect of changing roll temperature on the diameter of the journals and whether or not this change would adversely affect the oil-film clearance space allowed in the journal.

The permissible variation in oil temperature, which in turn affects the viscosity of the oil and the thickness of oil film, must be considered in the application of these bearings to rolling mills.

G. S. Warren.[7] This company has had a number of roller-bearing cold-roll strip mills working in a satisfactory manner for several years. On the two-high finishing cold-roll mills the roller bearings were not strong enough to make the reductions necessary, so that we had to install the plain babbitted bearings. We had also tried out roller bearings on the two-high hot strip mills and the results were a great improvement over the old type of brass and babbitted bearings, but the roller bearings were not strong enough to stand up under the heavy loads required to roll strip steel, and therefore the roller bearings had to be given up for this type of mill.

The company about four years ago installed a continuous hot strip mill with five stands of two-high roughing mills with four edging mills and six stands of two-high finishing mills. This mill was to roll strip up to 10 in. wide and from 0.035 in. thick in the narrow sizes to 0.065 in. thick in the wider sizes, and in lengths up to 1500 ft. The mill would do this on all sizes except on the light gages, where it was found impossible to hold the gage due to the brass and babbitted bearings. They tried out a greasing system on these bearings, which helped some, but did not correct the trouble.

When the Morgan Construction Company showed the design of the Morgoil bearings, these were installed on the last pass of the finishing mill, which has a delivery speed of from 1200 to 2400 fpm.

The trial proved a great success, as due to the fact that the necks of the rolls were made larger in the Morgoil bearings the rolls were much stronger and there was no wear in the bearings and the gage was uniform in cross-section and from end to end of the strip. The power required for this mill with the Morgoil bearings was from 50 to 60 per cent of the power required for the brass and babbitt bearings. The roller, who was watching the ammeter on the motor which drives this mill, finally loaded the mill up so that the ammeter was reading about the same as it would on the brass and babbitt bearings, and then one of the rolls broke. When the roll broke, he was reducing the cross-section of the steel about twice as much as he would have done with the brass and babbitt bearings.

This ended the test, as at this time the Sharon Steel Hoop Company replaced the six two-high mills with four four-high roller-bearing mills in order to roll strip up to 22 in. wide instead of a maximum width of 13 in., which was possible on the two-high mills.

The 22-in.-wide strip nearly doubled the load on the roughing mill, and so for a further trial a set of Morgoil bearings were installed in the No. 2 roughing mill, where the reduction was about 49 per cent. The bearings have been in operation for about six months. On a recent inspection of one of the bearings it was evident that there was practically no wear on the bearings, as at least 50 per cent of the surface of the babbitt still showed the tool marks.

The Morgoil bearing has made it possible to double the capacity of a rolling mill without any change to the drive; it has reduced the power required to roll steel 40 to 50 per cent. It has reduced the cost of lubrication, as the oil is in a closed system. Greasing systems on the other types of bearings make some savings, but still most of the grease is washed into the sewer.

S. M. Weckstein.[8] As to the development of the Morgoil bearing, there are a number of points on which it would be interesting to have the author's comments.

The design of the neck as shown permits of ideal construction to give maximum strength in bending. It would be interesting

[7] Chief Engineer, Sharon Steel Hoop Company, Sharon, Pa.

[8] Industrial Equipment Engineer, Timken Roller Bearing Company, Canton, Ohio. Jun. A.S.M.E.

to know the taper which is used on this neck and the diameter of the neck under the split threaded ring which is inserted in the neck. These dimensions will have an appreciable effect on the strength of the neck in torsion. In the case of a continuous mill the design would undoubtedly be satisfactory, but in the case of looping-type mills where three or more stands may be in line, the necks are apt to be weak. This has been proved conclusively on roller-bearing-equipped mills where due to the straight neck used the diameter under the split threaded ring was much greater than would be possible in the case of the tapered neck. In spite of this several necks have been twisted off when rolling was done in several of the stands at the same time. This occurred even though a saving in power of over 50 per cent was shown when the same mill was operated with plain-bearing-equipped rolls.

It appears from the design that pass adjustment is made through the plain thrust bearing. It is interesting to know just how close this adjustment can be made, since it depends on the oil film in the bearing. As regards the mechanical means of making this pass adjustment it is assumed that the methods now used with tapered roller bearings are being followed.

The type of closure used on the Morgoil bearing has been used for quite a number of years in connection with tapered roller bearings and has proved to be very successful both with grease and oil lubrication.

Very low coefficients of friction are claimed for the Morgoil bearings. It is interesting to know what arrangements are being made on both continuous and looping mills to take care of the backlash in the rolls, especially on bar mills.

The author has given no information on the capacity of the thrust bearings and on the methods of determining the thrust on various types of mills. This information appears to be quite important in the design of the bearing.

Since this bearing is designed primarily for use where roller bearings could not be applied because of lack of vertical height, it brings up the subject of two-high hot sheet mills. On these mills the roll bodies are heated and the necks assume temperatures as high as 400 to 500 F. Will it be possible to apply these bearings on mills of this type?

Author's Closure

Referring to Mr. Clark's questions, there are three conditions which might be considered when starting up a mill with preloaded bearings. Considering first the power aspect, it is a fact that the torque required to overcome the starting friction of a flood-lubricated bearing is much greater than the torque required to overcome running friction. The latter obviously is negligible; the former depends upon the elapsed time of shutdown and the smoothness of journal finish. As a matter of information, we have determined the torque required to overcome starting friction of flood-lubricated bearings under various preloaded conditions. To obtain such data it is necessary to first apply a small amount of current to the driving motor, and then gradually increase the amount until the motor starts.

The data thus secured are of interest and may be of value in some special application, but in most cases need not be considered. The reason is apparent when we realize how many mills are now easily started with the ordinary open type of plain bearing. In the usual mill construction there is lost motion in roll spindle couplings etc. Such play permits the driving motor to rotate a few degrees before all slack is taken up, and the stored energy, together with slight shock of impact, permits comparatively easy starting of a preloaded mill. We have found by tests that by applying, say, one-third full-load motor current, a preloaded mill is started without any difficulty. This is true in general for both two-high and four-high mills. In practically all cases there is enough friction between working and backing up rolls to easily start the latter rolls. In cold-rolling mills where the stock is lubricated, there is a possibility of a high polish being formed on the rolls which would cause slipping between the rolls at starting. To prevent such a condition, provision can be made in the bearing for the introduction of oil under high pressure. The necessary pump for this purpose is arranged to start automatically before current is applied to the main driving motor, and then stopped automatically as soon as the main motor starts. We have found from tests that such an arrangement reduces the starting friction to a very small value.

The second factor to be considered might be the wear on preloaded bearings when starting. Here, again, it is well to recall conditions that exist in mills with open-type bearings. The necks in these mills are none too smooth, but nevertheless if by some magic power we could have prevented all wear in such open-type bearings, while running, our problems would have been solved long ago, and there would have been no demand for a precision bearing. After studying many mill bearings, the author finds that most of the wear with the ordinary plain bearing occurs at the higher speeds. It is his firm conviction that with an enclosed type of flood-lubricated bearing, such as he has described, wear at starting will be negligible. From tests we have found that the oil film is reestablished within a fraction of a revolution after starting.

The third and perhaps the most important consideration is the effect of variations of oil-film thickness upon the gage of finished strip. As a starting point the author first investigated the variation of gage with speed in several stands of cold-strip mills equipped with roller bearings. Measurements were made of the thickness along a continuous length of strip while the mill was alternately run at high and low speed. It was conclusively determined that the material was heavier in gage when rolled at high speed than it was when rolled at low speed. The existence of a time effect was thus shown. As a further proof of this time effect it was found that the rolls actually "Brinelled" the stock when at rest. From these experiments we can state that a greater pressure is required to reduce the thickness of strip at high speed, and because of inevitable spring of the mill this results in a slightly heavier gage. The Morgoil bearing automatically tends to compensate for this added spring of the mill as the thickness of the oil film increases with speed. This naturally permits the rolling of a more uniform product.

The effect of change in roll temperature, and consequently change in neck and oil temperature, is to change the viscosity of the oil. The amount of change is a minimum, as the bearings are generously supplied with oil the temperature of which can easily be kept between desired limits. The change in minimum oil-film thickness is very small—about 0.0002 in. with the normal temperature changes. This change is negligible when compared with the changes in neck or roll diameter which now occur in mills with either plain or roller bearings.

The effect of moderate changes in total clearance, because of expansion, is also negligible as, within limits, the actual film thickness at the point of nearest approach, i.e., minimum oil-film thickness, is practically independent of the clearance. This we have determined by experiments with bearings having varying clearances.

Mr. Weckstein's questions regarding the sizes of the taper necks for the Morgoil bearing are best answered by reference to Fig. 13, which has been made accurately to scale from actual drawings. It will be seen that the strength of the neck near the roll is very much greater in the case of the Morgoil bearing than in the case of the tapered roller bearing, and even at the outer end the diameter under the split ring is still substantially larger.

The Morgoil bearing was developed primarily to meet pressing

needs which existed in strip mills. Since the introduction of this bearing the field of application has been, and is, continually broadening. The Belgian type of mill referred to by Mr. Weckstein is not built by our company for various reasons. Where

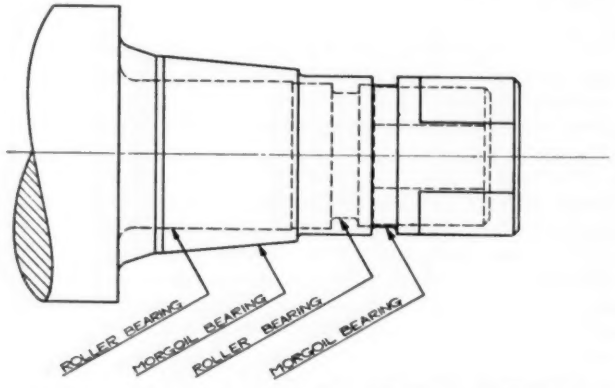

FIG. 13 COMPARISON OF NECKS FOR MORGOIL AND ROLLER BEARINGS, 14-IN. ROLL

looping is desirable, the individually driven staggered arrangement is considered much superior to the Belgian type. It is a fact that to date we have not had any inquiries asking for the adaptation of Morgoil bearings to this particular design of looping-type mill.

Regarding the accuracy of pass adjustment, the principles involved are exactly the same as those in adjustments for thickness of material, and these principles have been verified in practical experience in the field. Regarding the mechanical means of making this pass adjustment, there are several methods which have not been referred to in the paper. Some are external to the bearing; others are internal—that is, an integral part of the bearing. Where the Morgoil bearing has replaced the roller type, it is obvious that the same methods of pass adjustment have been retained for the sake of interchangeability.

Regarding back lash, we installed brakes in some of our early experiments, but removed them later as we found that they were not required. Possibly a superior coupling condition accounts for this result.

Regarding the capacity of thrust bearings, we at first attempted to secure a roller type of thrust bearing to be mounted in the same casing with the sleeve-type bearing. We soon found, however, that their capacity, at the required mill speeds, was very low, being only about 20 per cent of their static capacity. We then decided to adopt the centrifugally lubricated plain-disk thrust bearing in our initial installation. There were two things which we did not know at that time; one being the actual thrust in the mill and the other the capacity of such a bearing. It is a fact that we have not had any thrust-bearing failures to date. Where the thrust loads are known to be very severe, we have since taken extra precaution to put into practice the principles so clearly demonstrated by Professor Kingsbury and others. As the thrust-bearing surface can actually be considered a development of cylindrical bearing surfaces, the principles described in the paper relating to such bearings can be applied to the design of thrust bearings.

Since the paper was presented, our company has agreed to tackle the problem of rolling structural members without depending upon collars in the rolls for taking end thrusts. In this case these thrust loads have been quite accurately determined, and we feel that the time will soon come when the Morgoil bearing will do as much for the structural rolling mill as it has done for the strip mill.

Regarding two-high hot sheet mills, it is a question what the future will bring. Conditions are rapidly changing in this industry, and if a demand is evidenced, a suitable bearing can undoubtedly be supplied.

IS-55-3

Recent Developments in Merchant-Bar Mills

By G. L. FISK,[1] PITTSBURGH, PA.

After first discussing trade demands on merchant-mill products, the author points out the value of research and records in the making and rolling of steel. He then proceeds to discuss the factors affecting the quality of product in the merchant mill, and the items to be considered when selecting the type of merchant mill for a given range of products in a given plant. He next takes up the use and arrangement of vertical mills and the application of roller bearings to mill rolls, in case of existing and new mills, discussing also the economic and practical considerations involved. He then gives particulars of a new transfer-table design, and points out the uses and advantages of electric-driven flying shears. Finally, cooling-bed requirements to meet the needs of various merchant-mill products are then considered, as well as cooling-bed design and operation, objections to the double cooling bed, and double cold shearing from a single bed.

RAPID industrial progress in fields of mass production has been the indirect cause for corresponding developments in the art of rolling steel. Consumers are no longer satisfied with products of a more or less generally accepted standard, but demand merchant bars suited to specific and individual requirements. The steel manufacturers have found it to their advantage to provide extensive research departments not only to develop and determine the best grades of steel for various purposes, but also to observe their behavior in the subsequent manufacturing processes. This has enabled the steel manufacturers to trace to their sources such causes of troubles and rejections as can be remedied in the making and rolling of their products. These statements may be summarized as the tendency in recent years to achieve economy by giving special attention to the making and rolling of steels so as to lessen the expense of subsequent manufacturing operations.

To meet the exacting demands of the trade, merchant mills today are called upon to roll sections true to shape and size, within extremely small tolerances, which are free from injurious surface defects and are of homogeneous and definite grain structure. Although the fulfilment of these requirements depends on suitable mill arrangement and equipment and on good mill practice, it should be understood that the merchant-mill operation is no remedy for steel poorly made or which has been mistreated in prior rolling operations.

In case of unsatisfactory merchant-mill products, it is frequently a matter of contention whether the trouble originated in the steel-making department, in the bloom- or billet-rolling process, or in the finishing mill. Adequate records should be kept to show the complete history of the various steel heats. From such records the causes of defective mill products can be determined with certainty and mistakes can be avoided. Concerns which have engaged in this kind of research have been well repaid for their efforts, both in current economy and by being less dependent on the personal knowledge and experience of individuals. It is rather surprising that this has not been done to a greater extent, in view of the vast economic gain that accrues from definite knowledge as to how to make, heat, and roll in manufacturing a given product in a given plant. Steel plants differ materially in one part or another of their layouts and equipment, and often it is not safe to judge the experience in one plant by that in another, particularly in the case of merchant-mill products.

To confine ourselves to merchant mills, let us assume that billets of proper quality are available for rolling into finished bars. Good merchant-mill design and practice then demands that particular attention be given to the heating of the billets, the elimination of scale, the avoidance during the rolling process of stretching of the material and of severe twisting and scratching, the rolling to accurate shape and size, the controlling of the finishing temperature, the avoidance of scratching or other marking of the bars after leaving the mill rolls and during the cooling process, the handling of the hot bars to insure straightness of the product, and the controlling of the rate of cooling of the rolled bars. In addition the mill must be capable of rolling at high speeds and with a minimum crew and a minimum of delays and repairs in order to achieve the desired economy.

It is evident that all these requirements cannot readily be met, since some of them will react unfavorably upon others. For instance, a mill designed primarily for high-speed rolling, and consequently for large output, may, for this very reason, suffer as far as the quality of its product is concerned. A low-first-cost high-tonnage mill may prove very expensive to operate on a variety of relatively small orders. A mill somewhat higher in first cost and requiring a larger operating crew may be the more economical. In other words, each mill must be designed with particular consideration of the conditions in the plant where it is to be built and of the requirements of the trade which it is to serve.

Types of Mills and Their Selection

There are two types of merchant mills of particular interest to the modern steel plant, namely, the straightaway continuous mill and the semi-continuous mill. The selection of type of mill should be made on the bases of quality and kind of products, diversity of products, relative sizes of orders, number of mills in the plant, and ultimate cost of products.

We shall first consider the straightaway mill, of which Fig. 1 illustrates a recent installation. In the last several roll stands the pairs of rolls are alternately vertical and horizontal in order to avoid twisting of the material, and loopers are provided for vertical and horizontal looping so as to avoid stretching of the material between stands. One or more such mills may be justified in a large steel plant where the tonnage requirements for merchant bars demand several mills or where a large part of the mill products is suited for continuous rolling. In a plant of this character, the range of products assigned to each mill will be relatively limited, and the orders for the straightaway mill can be selected on the assumption that small orders, complicated sections, and sections requiring special attention can be diverted to other mills in the plant.

The straightaway mill has the advantage of low first cost and low operating cost. It is particularly well adapted for rolling of strip, skelp, flats, and angles, but also permits the rolling of other plain sections, including merchant bars. On the other

Contributed by the Iron and Steel Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

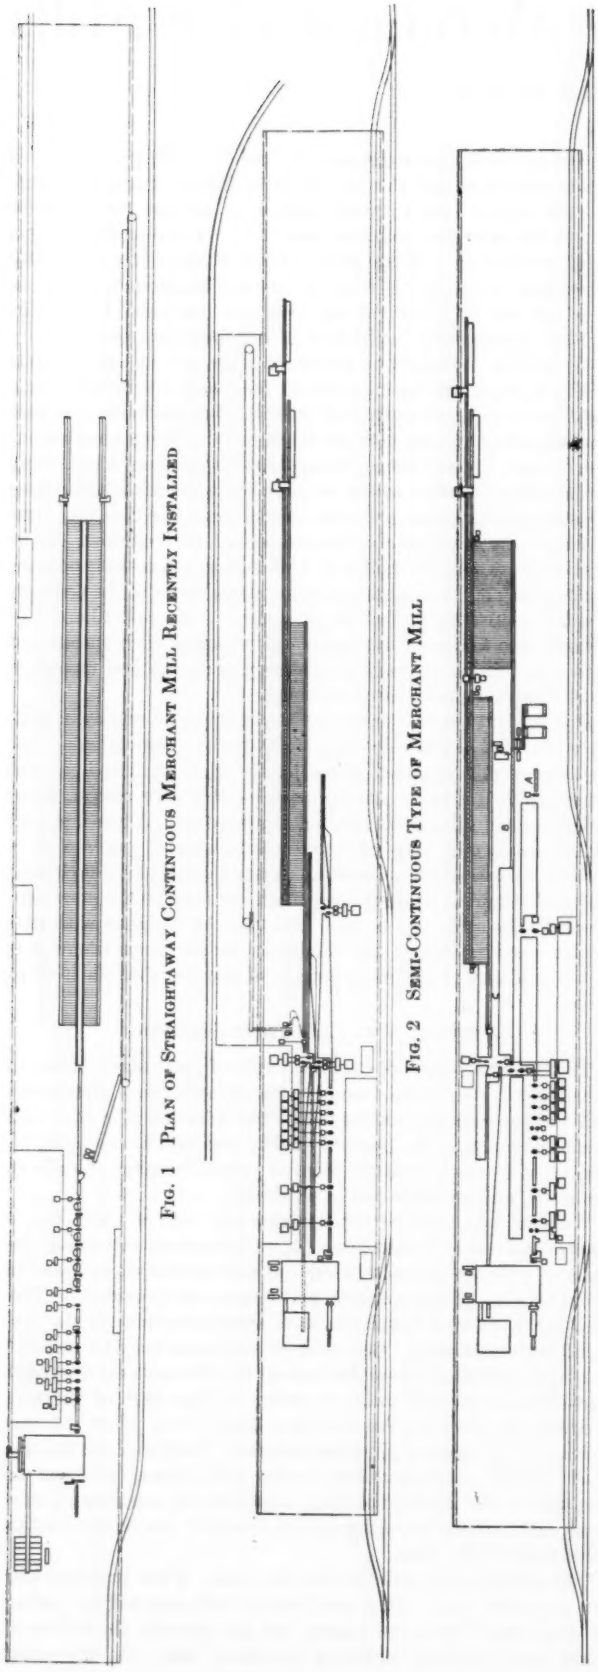

FIG. 1 PLAN OF STRAIGHTAWAY CONTINUOUS MERCHANT MILL RECENTLY INSTALLED

FIG. 2 SEMI-CONTINUOUS TYPE OF MERCHANT MILL

FIG. 3 ANOTHER RECENT INSTALLATION OF A MERCHANT MILL OF THE SEMI-CONTINUOUS TYPE

hand, it is by no means suited to, nor economical for, the conditions met with in the average merchant-bar plant.

To illustrate the shortcomings of the straightaway mill when used strictly as a merchant-bar mill, it is well to consider the proceedings in rolling a merchant round, for instance, as compared to the rolling of strip sections for which the continuous mill is so well fitted. The strip product must be accurate as to gage and width, but the thickness delivered by intermediary roll stands during the rolling process is comparatively unimportant. If the section delivered by one pair of rolls is somewhat thicker or thinner than expected, the speed of this pair of rolls can be adjusted accordingly and the discrepancy will automatically be compensated for in the succeeding pair of rolls. The mill rolls can therefore be set beforehand, and the successful progress of the bar through the mill becomes chiefly a matter of roll-speed control to maintain loops in the material between the several stands, and adjustment for gage in the last stands. The continuous mill is ideal for this condition. The width of the strip is readily controlled by edging rolls.

On the other hand, the ability to deliver a round bar true to shape and size from the finishing stand is dependent upon the delivery of an exact section from the next preceding or leading stand of the mill, and this section in turn is dependent upon the delivery of sections true to shape and section area from earlier stands. To set up a mill for the rolling of merchant bars requires numerous section adjustments involving several roll stands, and considerable skill is necessary upon the part of the operator. In a continuous mill the product of section area and delivery speed for the several roll stands must, by necessity, be a constant. Any adjustment in section area must therefore be accompanied by corresponding change in roll speed as in the case of the strip, previously referred to. But a change in section area in one stand may necessitate section adjustments of various magnitudes in several other stands, and the speeds of their respective rolls must also be changed accordingly. At the same time the roll speed must always be controlled, irrespective of any section changes, so as to maintain loops between the roll stands—this in order to avoid stretching of material, at least in the finishing end of the mill. The greater the number of continuous stands in a straightaway mill, the more these difficulties are aggravated. In other words, when using such a mill for rolling merchant bars it is subject to roll-speed control, just as in the case of the ordinary continuous mill for strip or flat stock, but the operator must also contend with additional and superimposed speed changes incidental to section adjustments.

Since it is admittedly a difficult and exacting art to produce high-grade merchant bars, even under the most favorable conditions, the additional burden imposed upon the roller in the case of the straightaway merchant mill is certainly not desirable. Although it is theoretically possible to attain as accurate a product as that of the semi-continuous mill, the chances of doing so are fewer. To set up a mill for any particular section is bound to involve considerable loss of time, as well as loss of steel in the form of scrap. In the case of often-repeated changes of section, these unfavorable factors will naturally adversely affect the economy of mill operations, and, in case of small and varied orders, the cost of rolling may become prohibitive.

Another disadvantage of the straightaway mill is the limited opportunity it affords for the making and breaking of scale to obtain satisfactory bar surface. Scale is formed on the bar by cooling in air, and in the ordinary close-coupled continuous mill the necessary time factor to produce the desired result is lacking.

Still another handicap of the continuous mill is the necessity for looping, which limits it to sections permitting such treatment.

The chief advantages of the straightaway mill, apart from those already referred to, are the feasibility of high delivery

speeds, i.e., a high rate of production, and incidentally the ability to roll to smaller section areas than in the case of the semi-continuous type of mill.

Figs. 2 and 3 illustrate recent installations of the semi-continuous-type merchant mill. Each has a straightaway roughing train with several stands arranged for continuous rolling. The intermediary and finishing stands of these mills are arranged to permit the material, in process of rolling, to run free after each roll pass, and transfer tables serve to deliver the bar from pass to pass.

Under these conditions the passes of the intermediary and finishing stands are entirely independent of one another, as far as speed is concerned, and the roller is free to adjust the passes individually as suits his requirements in obtaining an accurate product. The continuous passes of the roughing train are comparatively few in number, and for that reason are easily adjustable to the required accuracy.

With the freedom of action thus obtained the roller can quickly change from one section to another, and is generally bound to produce more accurate products with less scrap loss. This type of mill is also well adapted to the rolling of intricate sections not suited for looping. The transfer tables can be used to delay the bar in process, in order to control the scaling of the bar as well as the finishing temperature of the product. Furthermore the rolling speed of the intermediary and finishing trains is independent of that of the roughing train. Small sections, which must be looped or repeated through the intermediary or finishing roll stands to conserve heat, can for that reason be finished at the temperature best suited to each particular product. These are matters of considerable importance, as affecting the surface and the structure of the product.

To summarize: The semi-continuous mill is the better for high-quality products, also when a great diversity of products must be rolled on one mill, or when the tonnages of the individual sizes rolled are comparatively small. In other words, such mills are more generally applicable to conditions as they exist in the trade today. The straightaway mill has its place in large steel plants, where other mills are available for specialties and jobbing orders; that is to say, where the work can be selected to suit the mill.

Vertical Mills

The reduction of a square billet into a square bar of smaller section, which is the usual function of the merchant-mill roughing train, is accomplished by reducing first one axis of the bar and then the other, and by repeating this process until the square of desired size is attained. For this reason the continuous roughing trains shown in Figs. 1 and 2, with all rolls horizontal, necessitate the use of guides to twist the bar between some of their roll stands. Unless the stands are spaced sufficiently far apart to minimize the severity of the twist, the structure of the material may be harmed in the operation or the guides may scratch its surface. A fair portion of the rejected product from the ordinary merchant mill is traceable to the twist guides.

The vertical mills with overhung rolls, indicated in the roughing train of Fig. 3, are principally intended for edging work on flat material, and the first one also serves for the breaking of scale. Edging mills of this type, with one or two roll passes at or near the pass elevation of the horizontal rolls, are also usable, and have been used to advantage, in roughing trains, to avoid twisting, when the passes required in the vertical rolls are few in number.

In case of small sections rolled at high speed, the use of twist guides conduces to difficulties and scrap loss. The twisting and guiding of a small bar necessitates small guide clearances, and any slight resistance in the path of a small-sized bar traveling at high speed may cause a cobble. The finishing end of the straightaway mill shown in Fig. 1, in contrast to the finishing ends of the semi-continuous mills in Figs. 2 and 3, would require twist guides if all its rolls were horizontal. Furthermore, since looping is required, for reasons already stated, it would be necessary to loop twisted sections between some of the roll stands. These difficulties are avoided by the use of vertical mills of recently improved design.

The needs of the finishing end of the continuous merchant mill call for vertical mills with full-sized rolls, supported in bearings at both ends, and with a full complement of roll passes, just as would be provided in the case of horizontal rolls. The rolls must be adjustable up or down to bring any pass to the elevation of the pass line of the preceding and succeeding horizontal rolls. The mill must be capable of sidewise adjustment to bring any pass in the vertical rolls into alignment with any pass line of the horizontal rolls. Furthermore it must have means for accurate roll adjustment to pass opening, and for moving one of the rolls longitudinally with respect to the other. Another requisite is that roll changing should be as easy as in the case of horizontal rolls. The mill should be readily accessible to the operator and should not extend beyond the other roll stands, particularly on the working side of the mill, where it may in that way be an obstruction to operations and visibility in the mill as a whole.

A vertical mill, designed with these principles in mind, is shown in three views in Fig. 4. Roller bearings appear to be essential in this mill, in that they can be enclosed so as to avoid any possibility of scale getting to the bearings. Each roll is suspended from its top bearing and can be removed individually with its bearing boxes, merely by releasing the spring tension holding it in place, and by loosening and moving a clamp. It is also possible to remove both rolls, together with a specially designed roll housing *A*, by removing the cap *B* and loosening the clamping screws *C*. The mill proper is accessible on all sides, having its driving mechanism located in a pit below the floor level. Notwithstanding this arrangement, the pinion housing is removable as a unit, and any machinery part may be easily reached in case of repairs. One of the principles of the design, however, has been to provide against wear and replacements of parts by the use of roller bearings and high-grade materials throughout.

Roller Bearings Vs. Plain Bearings for Mill Rolls

One of the most interesting recent developments is the application of roller bearings to merchant-mill rolls. Attempts have been made, with more or less success, to substitute roller bearings on the rolls of existing mills, but such proceedings usually involve serious difficulties. Roller bearings take up more space than plain roll-neck bearings, making it necessary to reduce the diameter of the roll neck to compensate for this difference, or a good portion thereof. Since the roll neck is frequently the weakest part of the roll, it goes without saying that the substitution of roller bearings for plain bearings on existing mills is most frequently not practicable. Even when it can be done without seriously weakening the rolls, the housing design, originally intended for plain bearings, does not readily lend itself to a practical solution of the roller-bearing application. Roll changes and roll adjustments become cumbersome, and the change-over to roller bearings, principally because of the necessary and expensive alterations to existing roll equipment, is too costly to warrant serious consideration.

In the case of a new mill, where the designer has full freedom, the picture is a different one and conditions may justify the use of roller bearings on the roll necks, provided full advantage be taken of the opportunities incidental to the use of such bearings.

The roller bearing does not show any wear as compared with the plain mill bearing. This fact can and should be taken advantage of, to save time in aligning and setting the rolls to ap-

proximately correct position. Furthermore, as soon as discrepancies in longitudinal and radial roll directions have been ascertained, from a trial bar or otherwise, it is a relatively simple matter, if the roller-bearing application has been designed with this purpose in view, to make the exact adjustments to the required pass opening. The roller bearing therefore offers the opportunity of prompt and exact roll adjustments by aid of indicators, and largely without the cut-and-try process incidental to the use of plain bearings. When the rolls have been adjusted to the correct position they will stay in this position, thanks to the absence of bearing wear. Thus the operator has only to consider the wear in the pass itself during the subsequent rolling operation. This of course is of decided importance, and an advantage which will be readily appreciated.

In case of a new mill, the additional space required for roller bearings as compared with plain bearings can be provided by increasing the roll diameter correspondingly, so that what would be a 14-in. mill, for example, in the case of plain bearings, will become a mill with 18-in.-diameter rolls when using roller bearings on the roll necks. This will naturally increase the roll cost, and also the cost of the mill machinery to some extent. The necessity of grinding the roll necks to exact size is another unavoidable expense connected with the use of roller bearings.

On the other hand, the power consumption with roller bearings may be reduced from 25 to 50 per cent, depending upon the rolling speed and the shape and nature of the material rolled. To offset the high cost of rolls and mechanical equipment, the reduced motor cost with roller bearings deserves serious consideration. The tendency in modern merchant mills is toward individual motor drives and direct current.

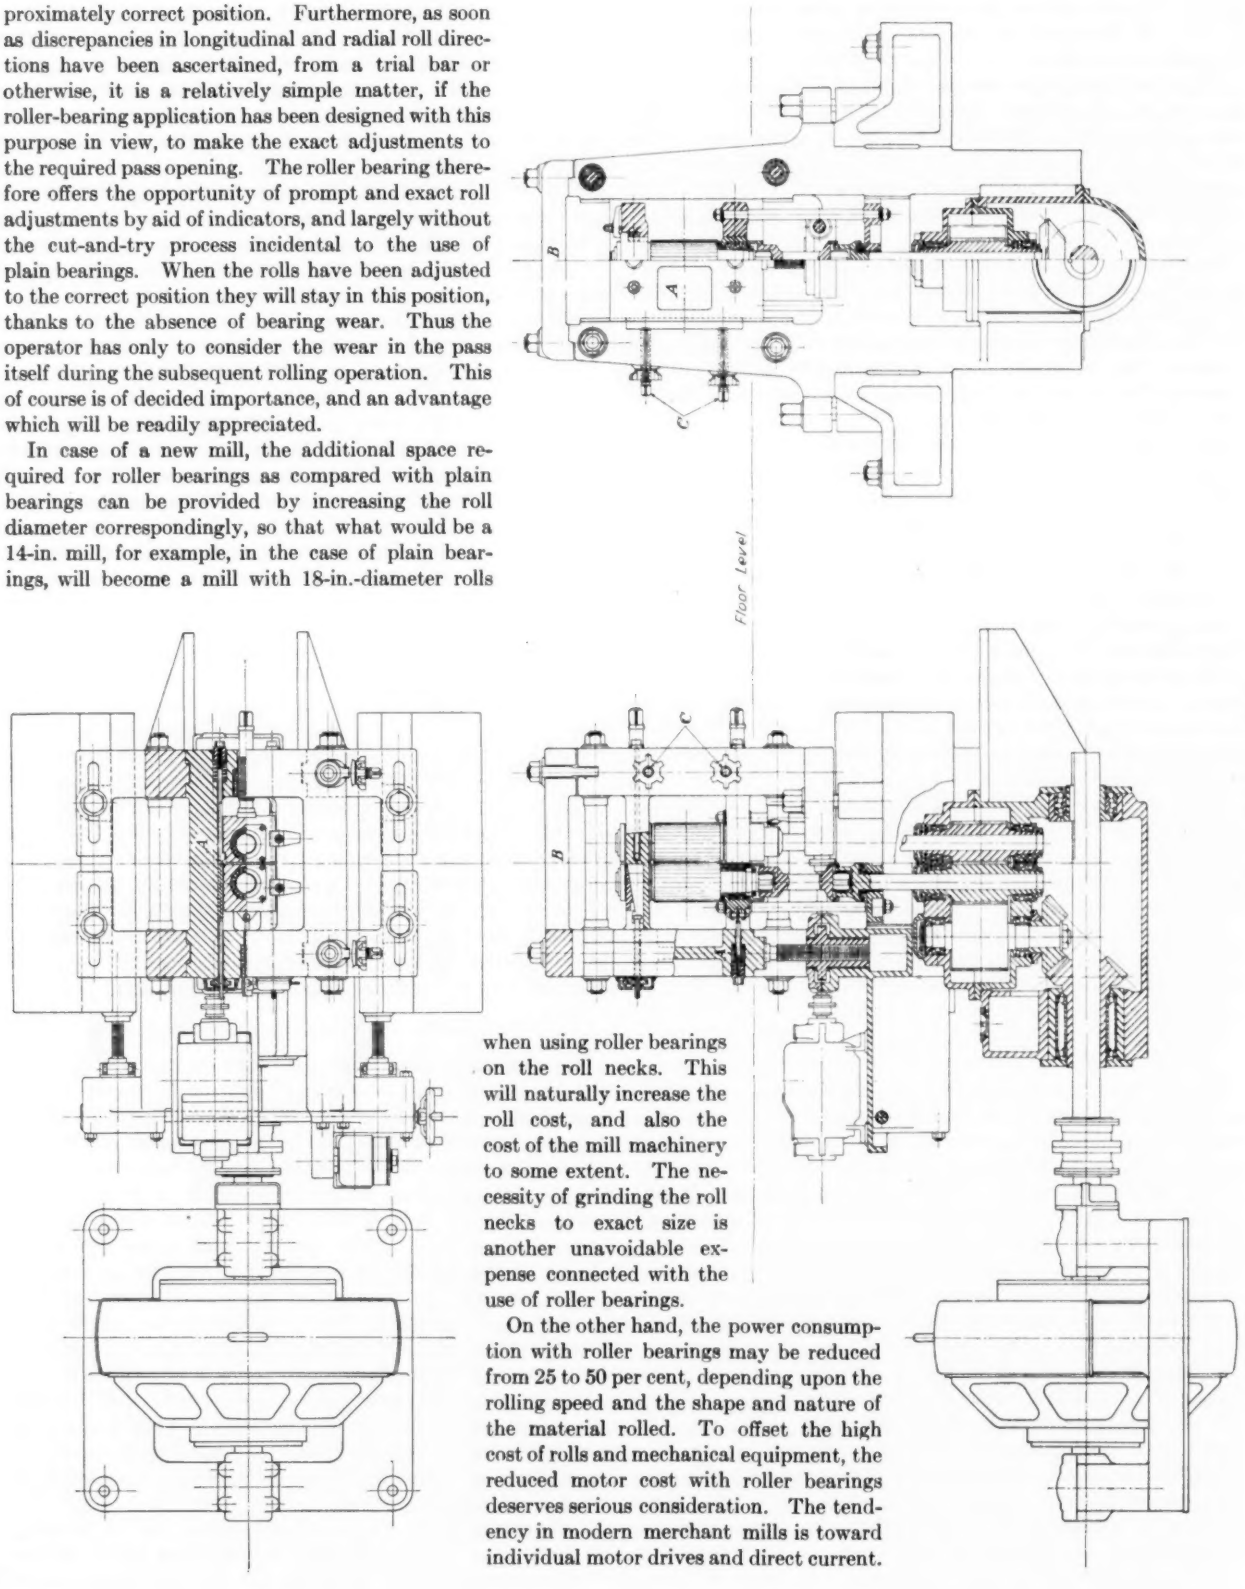

FIG. 4 VERTICAL MILL

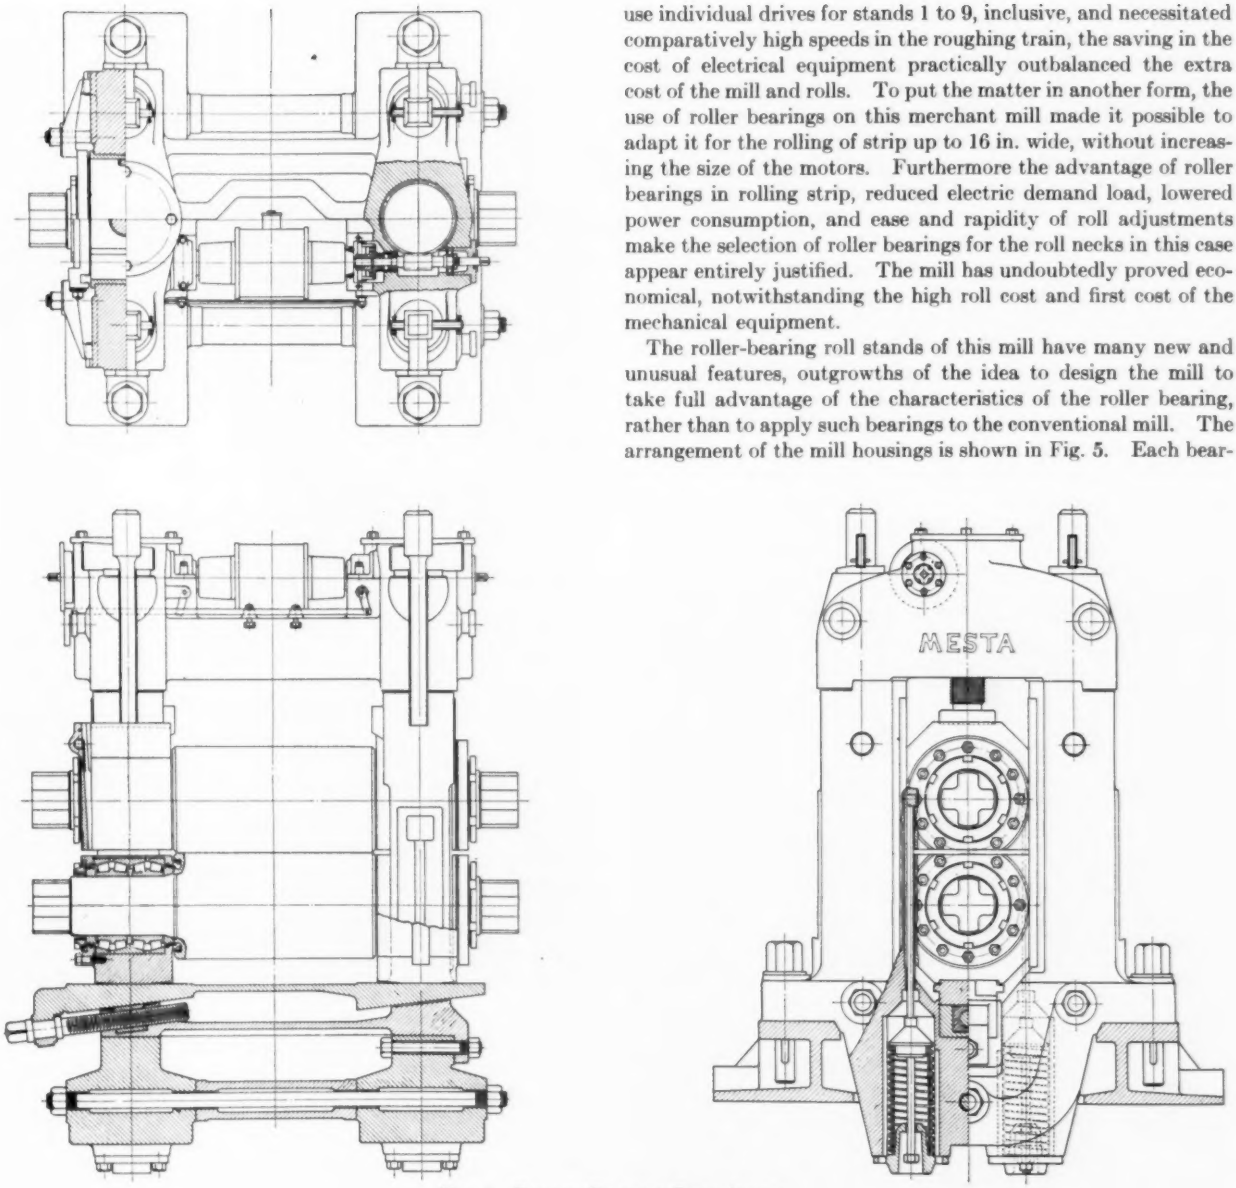

FIG. 5 ROLLER-BEARING ROLL STAND

Any saving in size of motors, therefore, may mean a substantial reduction in the first cost of the electrical equipment.

It is yet too early to predict to what extent roll-neck roller bearings will invade the merchant-mill field, but considerations may exist, apart from those already mentioned, which favor roller bearings. A notable example is the mill recently installed and shown in Fig. 3, which is equipped with roller bearings on the roll necks of stands 1 to 12, inclusive. These stands deliver to two outlets, marked *A* and *B*.

One of the chief problems here was to provide for exceptional diversity of product. Nominally a merchant mill delivering to outlet marked *C*, which covers the range from $^3/_4$-in. up to 3-in. rounds and corresponding sections, the outlet marked *B* is provided to cover rounds from $2^1/_4$ in. up to $4^1/_2$ in. diameter and corresponding sections. Should the market for such products not permit satisfactory mill operation, the outlet marked *A* is usable in rolling strip and flats up to 16 in. wide.

Thanks to these unusual demands, which made it imperative to use individual drives for stands 1 to 9, inclusive, and necessitated comparatively high speeds in the roughing train, the saving in the cost of electrical equipment practically outbalanced the extra cost of the mill and rolls. To put the matter in another form, the use of roller bearings on this merchant mill made it possible to adapt it for the rolling of strip up to 16 in. wide, without increasing the size of the motors. Furthermore the advantage of roller bearings in rolling strip, reduced electric demand load, lowered power consumption, and ease and rapidity of roll adjustments make the selection of roller bearings for the roll necks in this case appear entirely justified. The mill has undoubtedly proved economical, notwithstanding the high roll cost and first cost of the mechanical equipment.

The roller-bearing roll stands of this mill have many new and unusual features, outgrowths of the idea to design the mill to take full advantage of the characteristics of the roller bearing, rather than to apply such bearings to the conventional mill. The arrangement of the mill housings is shown in Fig. 5. Each bearing box, with roller bearings complete, is built in the form of a dirt-proof unit, which is slipped on or off the roll neck as one piece. Each roll has provisions for locking the inner bearing sleeves to its roll necks, to prevent bearing-box movement on the neck in the longitudinal direction, except to the extent of the running clearances of the roller bearings. At the same time, the roll is free to revolve, together with the inner bearing sleeves, while the bearing boxes are held against rotation in the housings of the roll stand.

The bearing box for the free end of the roll is provided with flanges by means of which it may be clamped in the ordinary manner to the roll housing; whereas the bearing box at the driven end of the roll has no flanges, but is free to move with the roll longitudinally in the housing to take care of roll expansion. The bearing boxes of the bottom roll rest on a casting with a horizontal top surface but movable up and down, by wedge adjustment, to bring the bottom roll to the desired pass position. With this arrangement the bottom roll always stays horizontal, although

adjustable to any required elevation. The top roll and its bearing boxes are balanced by means of spring cartridges located in the base of each roll housing. The housing cap is made unusually heavy, for the purpose of overcoming the spring tension of the top-roll balance, so that it can be set and wedged in place with minimum delay, and without giving consideration to the position of the screwdown screws. The adjustment of the top roll is effected against the tension of the roll balance by means of a motor-driven screwdown. The motor is permanently geared to one of the screws and to a dial indicating the screw position. A hand-operated clutch throws the other screw in or out of engagement with the same motor. It will be understood quite readily that by this arrangement either end of the top roll can be adjusted up or down to any exact dimension readable on the dial. The alignment of the rolls in the longitudinal direction for a given pass is accomplished by means of a small adjusting shaft on the top bearing box on the open side of the mill. An index on this shaft is graduated in 0.005-in. divisions and permits longitudinal adjustments of the top roll with respect to the bottom roll within a total movement of $^1/_4$ in.

It will be noted that the bearing boxes are mounted on the rolls prior to their insertion into the roll housings. The roll assemblies are lowered into the housings in the customary manner, and are then clamped into position as already described. To exchange rolls, the guides are taken away, the cap is removed, the clamp bolts are loosened, and both rolls with their bearing boxes are then free for removal, with one lift, by an overhead crane. The new rolls are stacked in pairs and also inserted into the mill with one crane lift.

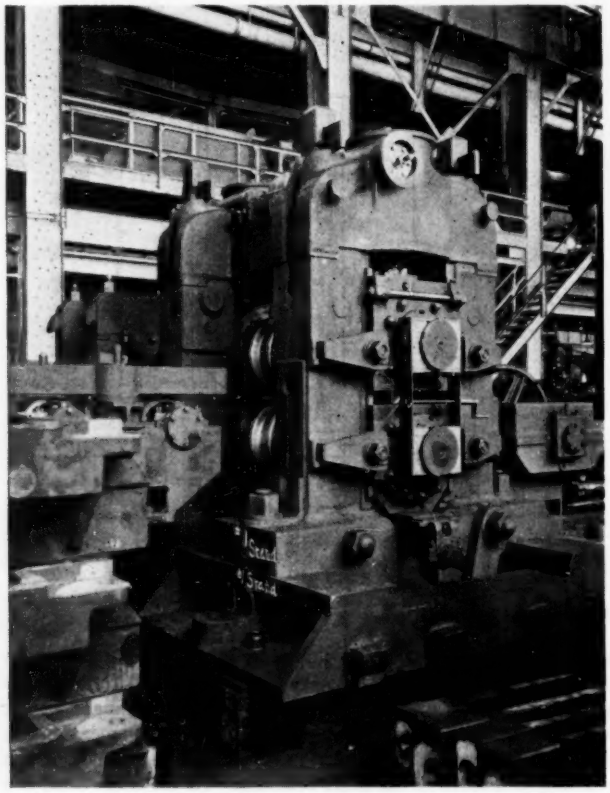

FIG. 6 VIEW OF ROLL STAND SHOWN IN FIG. 5

With the roll housings properly designed, it appears that roll changing in mills with roller bearings can be carried out as easily as in mills with plain bearings. Roll adjustments are easier and more definite with roller bearings, and a roll set-up can be maintained indefinitely, except for adjustments to compensate for pass wear.

A sufficient number of spare bearing boxes, with bearings complete, must be provided in the case of the roller-bearing mill, to allow mounting of bearings on rolls as they are scheduled for use. This work can thus be done prior to the actual roll-changing operation, unnecessary delays can be avoided, and the cost and time of roll changing can be made to compare favorably with these items for the plain-bearing mill. The additional investment in roller bearings should be offset to a large extent by wear and replacements of plain metallic bearings, since the roller bearing is extremely long-lived when it has ample capacity with which to avoid overloading. At the same time, the adoption in recent years of lignum-vitae and non-metallic compositions as materials for plain roll-neck bearings has in many instances very materially reduced the bearing wear and the cost of bearing maintenance.

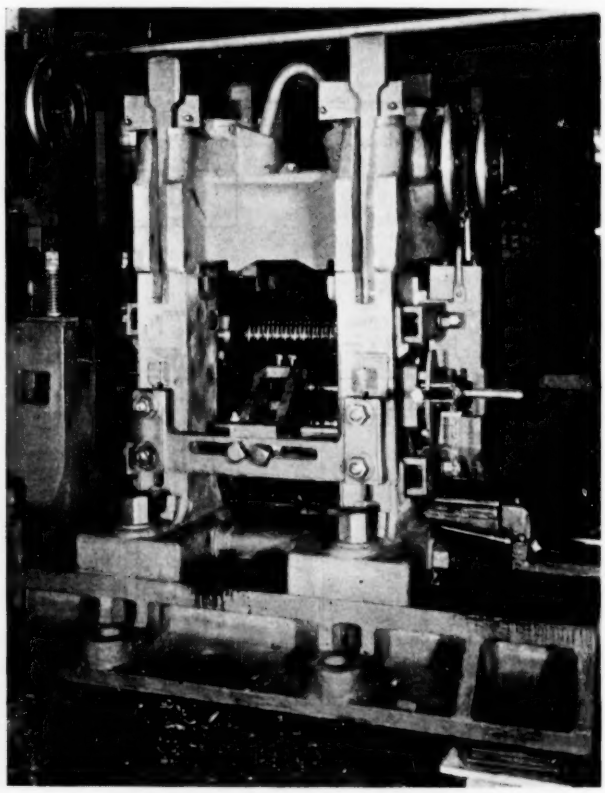

FIG. 7 ROLL STAND WITH PLAIN ROLL-NECK BEARINGS AND HAND-OPERATED SCREWDOWNS

Fig. 6 is reproduced from a photograph of the roller-bearing roll stand shown in Fig. 5. For comparison, an up-to-date roll stand with plain roll-neck bearings and hand-operated screwdowns is illustrated in Fig. 7.

TRANSFER TABLES

The Y-shaped transfer tables shown at the intermediary and finishing roll stands of the mill illustrated in Fig. 2 are of notable construction. Each of these tables serves to receive the bar as it is run out from one stand, transfer it sidewise, and deliver it in the opposite direction to the succeeding stand.

Tables for this purpose have in the past been made with skewed rollers, whereas the tables here referred to have all the rollers parallel with the axes of the mill rolls. The rollers nearest the

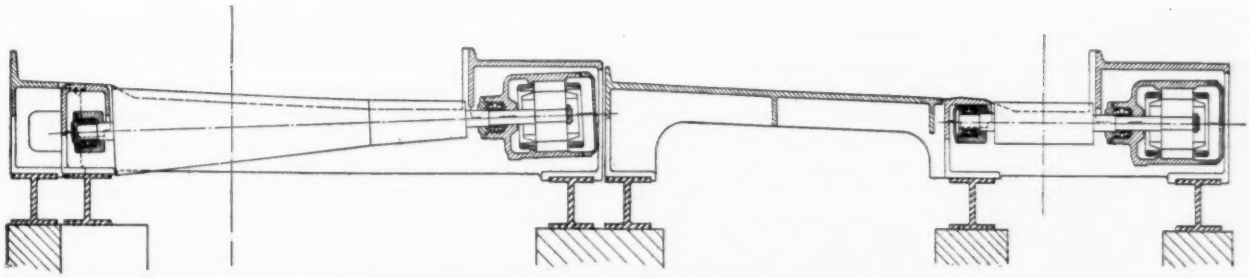

FIG. 8 CROSS-SECTION THROUGH TWO ADJOINING TRANSFER TABLES

mill are tapered and of such length as to cover the distance between the particular roll stands the table is serving. The length of the tapered rollers decreases with increasing distance from the mill rolls to form a triangular-shaped table section, which is followed by a table section of narrow, uniform width with straight rollers. A cross-section through two adjoining tables is shown in Fig. 8, the section being so taken as to show the longest tapered roller in one table and one of the straight, short rollers in the other.

Each of the tapered rollers has two tapers, a more pronounced one at the receiving end and a less pronounced one at the delivery end. The width of the less pronounced taper is uniform for all the rollers, and the diameter at the center of the slight taper is equal to the diameter of the straight rollers. The slightly conical portions of the tapered rollers are set horizontal and level with the straight rollers, thus causing the tapered rollers to be mounted with sloping axes, but all on a uniform slope. Apron plates provided between the rollers make a continuous and practically level floor, suitable for the transfer of bars, but also adapted for use as a looping floor. All the rollers of the table are driven by individual motors, operated from a single electric control. When operated in either direction, all the rollers run at the same, but variable, r.p.m.

The transfer table is controlled in the following manner: The table rollers are operated in the direction of bar delivery, with the straight rollers running at, or slightly above, the bar-delivery speed. Immediately the entire bar is delivered to the table the rollers are reversed, but a timing relay is provided in the electric control to cause the straight rollers of the table to reverse a second or so later than the tapered rollers. During this time interval the bar in transit will be partly supported on straight rollers running in one direction and partly on tapered rollers running in the opposite direction. The bar, seeking the path of least resistance, will promptly move toward the small ends of the tapered rollers. By this time both the straight and the tapered rollers will be operating in the same direction to deliver it to succeeding mill rolls.

FLYING SHEARS

Electrically driven flying shears have been developed in recent years for the cutting of bars up to 4 in. square. Such shears may be used for dividing or cropping bars during their progress through the mill. If it is desired to crop the front end, or rear end, or both ends of the bar after its passage through a given roll stand, load relays can be provided in connection with the motor for this stand to do such cropping automatically. Electric time relays furnish the means for controlling the timing of the cropping operation, i.e., the length of crop.

A recent development is the use of a flying shear following the finishing stand of a merchant mill, not only to divide the bars into cooling-bed lengths but also to cut test pieces from the ends of bars on their way to the cooling bed. Such a shear used in mill layouts, Figs. 2 and 3, is illustrated in Fig. 9. It is of the rotary type, and with a bar running through the shear can be accelerated to bar speed by the time the knives begin the cutting operation. It was formerly necessary to divide the bar into cooling-bed lengths farther back in the mill, where the bar speed was low enough to permit cutting with the flying shear equipment then available. The cutting of test pieces by a flying shear close to the finishing stand permits the roller to gage the bar without going to the cooling bed. Except for small-sized bars, which could be cut with hand-operated snapper shears, it was formerly necessary to gage the mill products at the cooling bed, often an awkward operation and one involving considerable loss of time.

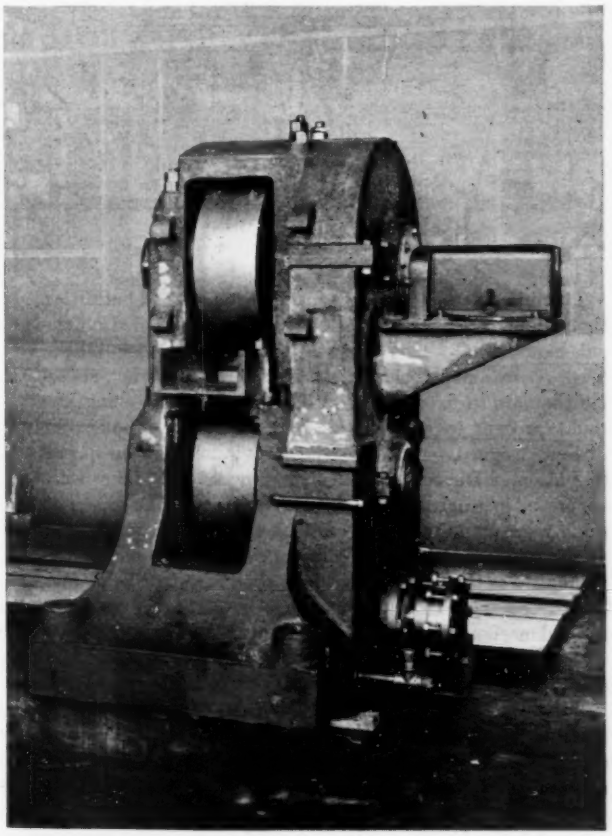

FIG. 9 FLYING SHEAR

COOLING BEDS

In days of old, the product of the merchant-bar mill was usually delivered from the finishing stand into a trough. The ends of each bar were manually inserted into the heads of an apparatus for stretching, to obtain the necessary straightness, and the bar

was then dropped upon a sloping-skid bed to cool slowly in contact with other bars. This was common practice, at least with square and rectangular sections. Rounds, straightened in the same manner, were usually permitted to roll down the sloping-skid bed onto a secondary bed of stationary horizontal skids. The first round delivered to the secondary-skid bed would be laid straight, and parallel to the mill delivery trough already referred to. Subsequent bars would roll by gravity until stopped by making contact with bars already deposited on the secondary-skid bed. The cooling of the rounds, therefore, was also effected at a slow rate by maintaining contact between the bars during the cooling process. Having collected a group of bars in this manner, a part thereof were moved on for shearing and the remainder were moved forward to make room for additional bars from the mill. In other cases, the mill was operated to collect a group, or pack of bars, and then allowed to remain idle until the bars were sufficiently cooled to permit them to be moved, making space for another pack. The use of a double bed permitted the delivery of bars to one bed while bars were cooling on the other, and vice versa.

The introduction of the mechanical cooling bed permitted the rolling of longer lengths than could be handled on the old hand beds. This meant the use of heavier billets, fewer operations in the mill, and less scrap loss when shearing the bars to fixed lengths. The mechanical cooling bed could be built to cool any desired tonnage per hour, but it was designed for cooling the individual bars in spaced formation. During the cooling process the bars were supported in grooves formed by a series of spaced skids. The skids were made of rough castings and the straightness of the grooves governed the straightness of the bars cooled therein. Not only was the straightness of the product impaired by inequalities of the skid castings, but the wear of the moving parts of the bed mechanism, or the replacement of worn parts, would cause further misalignment in the grooves and distortion of the bars subject to cooling.

For certain classes of products, such as screw stock and spring flats, for instance, the rapid cooling of the bars, when carried in spaced formation on the mechanical bed, was detrimental. The annealing effect obtained with the old hand bed, where the product was cooled in pack formation, would soften such classes of product and make them better suited to subsequent manufacturing operations.

Attempts have been made to pack-anneal spring flats on mechanical beds by collecting them in small groups, and then handle these groups in the ordinary manner in the grooves of the bed. This method of pack annealing, however, has the disadvantage that the outside bars in each group cool at a faster rate than the interior bars, causing the mill product to be non-uniform in hardness. As far as rounds are concerned, the ordinary mechanical cooling bed has no facilities for their pack-annealing, i.e., for the slow cooling of rounds in pack formation. It should also be noted that the rapid cooling of bars in spaced formation, with free access of air to each individual bar, is apt to cause more scaling of the bars than when they are cooled in contact with one another.

To overcome the difficulty of non-uniform hardness encountered with small individual packs, beds have been devised for continuous mechanical pack-annealing, but most of these designs are predicated on the use of a separate bed for the pack-annealing of spring flats only, and are not adapted for the packing of rounds or the handling of mill products which do not require pack-annealing.

With increasingly exacting demands on mill products, particularly in the case of relatively high-carbon, special, and alloy steels, it appears that the mill operator must be in a position to control the grain structure of his product. To this end he requires facilities to govern the rate of cooling, not only in the case of flats, but also in the case of squares, rounds, and other sections. A given

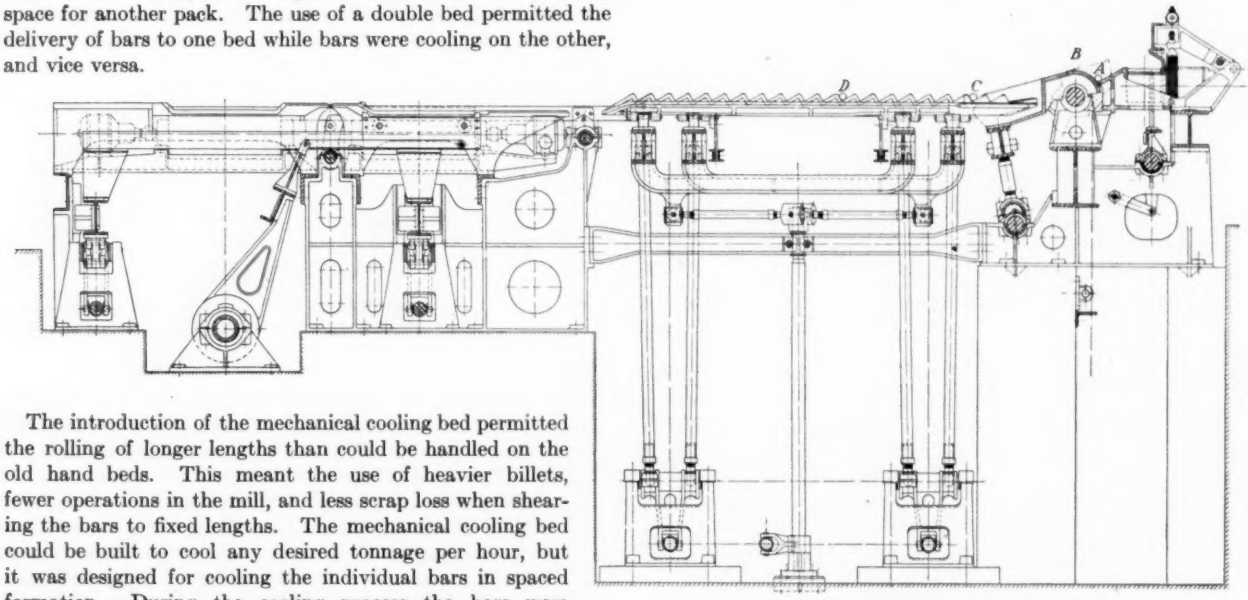

Fig. 10 Recent Design of Cooling Bed

cooling bed may therefore be called upon to handle any of these sections in spaced formation, or in pack formation, to suit the requirements of individual orders. Few steel plants can afford to build single-purpose mills or to limit the scope of a mill to the range of products for which the ordinary cooling bed is adapted. Certain grades of steel, when cooled in pack formation, will camber decidedly, due to contact with hot bars on one side and open-to-air cooling on the other. Such bars, when permissible to do so, should be cooled individually while supported in grooves in two directions. Other bars of irregular cross-section are likely to acquire a decided camber during the cooling process, or may be rolled with a camber to cause them to be straight when cooled. Such bars should be handled on a flat bed. In order not to limit the scope of the mill, therefore, a single bed should be adapted for the cooling of bars in both spaced and pack formation, and should preferably have its surface adjustable to meet the requirements already outlined. Provision must also be made to avoid scratching and marking of bars during their handling to and by the cooling bed.

A cooling bed recently installed and built to meet these requirements is shown in cross-section in Fig. 10. The roller table conveying the rolled bars from the mill to proper position alongside the cooling bed has cylindrical rollers flanged at one end and placed at a slight skew, in order to cause the bar to align itself

along the flanges of the rollers. The skewing of the rollers serves to keep the bar from wandering sidewise on the face of the rollers, which would cause it to lie crooked prior to the kick-off operation. In such event the kick-off arms would strike certain portions of the bar ahead of other portions and would be likely to cause kinks and twists in the rolled bars during the kick-off operation. As already explained, this is avoided by skewing the rollers, and their flanges serve to keep the bar out of contact with the side guard while the former is being conveyed to position alongside the cooling bed. The straight rollers are an improvement over the tapered ones frequently used in similar tables, in that the different surface speeds at various points of the taper tend to twist the hot bars, such as squares, during their travel. Any twisting of the bar around its own axis is thus avoided by the use of cylindrical rollers.

The stopping of the bar on the run-in table alongside the cooling bed is accomplished by lifting the apron plates above the table rollers. The apron plates, in their lifted position, are arranged to support the bar for its entire length, except for the necessary gaps at the table rollers. The top surfaces of the aprons are smooth-machined and apply a gentle frictional resistance for practically the entire length of the bar, to avoid scratching or marking of product.

From the cooling-bed run-in table, the individual bars are swept sidewise onto the cooling bed by means of a series of spaced kick-off arms. These kick-off arms and the lifting apron plates are operated from a common drive. They are so interconnected that the apron plates will lift and allow the bar in transit to come to rest before the kick-off arms engage the bar and sweep it onto the cooling bed. In this manner any nicking or marking of the hot bars by the kick-off arms is avoided. The motion imparted to the kick-off arms is such that their free ends sweep the bar off the run-in table and then return beneath the surface of the table to their point of starting. By virtue of this arrangement of the kick-off mechanism, a bar can be delivered from the mill onto the aprons of the cooling-bed run-in table and behind the kick-off arms while these arms are engaged in sweeping the preceding bar onto the cooling bed.

The kick-off arms deliver successive bars onto an apron of sufficient slope to cause the individual bars to slide by gravity to a stop, against which each bar is aligned by impact, to insure straightness prior to delivery to the cooling bed proper.

The cooling bed has two sections. A preliminary section serves for the pack-annealing of squares, flats, and other rectangular sections, but is also useful in the handling of rounds, as will later be set forth. A secondary section provides for the cooling of bars in spaced formation and also for the packing of rounds.

Referring to the primary-bed section, the packing of flats, which should be cooled on edge in order to insure straightness, is accomplished by the use of counterweighted dogs, or abutments, against which the first bar delivered is deposited for sidewise support against overturning. Succeeding bars from the mill are deposited in identically the same position as the first bar, causing the dogs and the bars previously deposited to yield or move a distance equal to the thickness of each bar delivered. In this manner a pack of bars is formed with the edges of the individual bar resting on the surface of the primary bed. When the pack has attained sufficient size to be self-supporting, the dogs automatically withdraw below the bed surface. Further additions of bars will cause the pack to grow until it has attained a size limited by the width of the primary-bed section. The bars first deposited will then slide off the end of the primary bed onto the secondary bed as additional bars are added to the pack. The pack-annealing operation thus becomes continuous, in that bars will then be discharged at the delivery end of the primary bed at the rate at which bars are added to the opposite end of the pack. The width of the primary section is sufficient to complete the annealing operation and allow the bars to take a permanent set before they are delivered to the secondary-bed section.

The secondary bed has two sets of carry-over bars, one set balanced against the other. By such balancing of the moving parts they can be made relatively light, in that the only work performed in operating this bed section is to overcome the friction of moving parts and to lift the material deposited upon the bed. Each carry-over bar in both sets has two working faces, one straight and the other notched. A motor-driven turnover will quickly move one or the other of these working faces into operating position, thus producing in one case a notched bed surface suited for advancing bars from notch to notch, and in the other case giving the bed a flat top surface on which bars may be advanced in pack formation or spaced, as the case may be.

To illustrate the adaptability of this bed, its operation with reference to handling of various grades and shapes of product should be noted. Let us first consider the cooling of rounds in spaced formation. Delivered by the kick-off arms onto the cooling-bed apron, the bar will receive a preliminary straightening when stopped by impact in position *A*, Fig. 10. It will then be lifted to position *B*, to roll by gravity down the slope of the primary bed section to position *C*, in a groove of the carry-over bars of the secondary-bed section. The free rolling of the bar down the primary-bed section is an excellent method for straightening rounds. Successive rounds are carried forward, groove by groove, from position *C* on the secondary-bed section, from which section they are finally discharged, one by one, onto shuffle bars, for group assembling in the customary manner prior to shearing.

The working surfaces of the entire bed are smooth-machined, including the notched and straight working faces of the carry-over bars. Marking of the product is avoided by these means, and a straight round, delivered to groove *C* of the secondary bed, can be maintained straight throughout the cooling process by avoiding the irregularities of unmachined castings. To maintain the alignment of the machined grooves of the secondary-bed section, this bed is made up of short individual units, each readily adjustable to move the carry-over bars of any unit longitudinally in either direction, or up and down, as may be required to maintain exact groove alignment. This adjustment can readily be made by the aid of a wrench without interruption to the operation of the bed.

When desiring to cool rounds slowly in pack formation, the first round delivered to position *C*, Fig. 10, is immediately carried forward, groove by groove, to position *D*. The adjusting motor of the carry-over bar is then operated, changing the secondary bed to a flat surface and leaving the first round as shown in position *D*, Fig. 11. The next round delivered from the mill, when caused to roll down the slope of the primary bed, continues its rolling until it makes contact with the first bar deposited on the secondary bed. When a small group of bars has been assembled in this manner on the secondary bed, it is moved forward sufficiently to make room for additional bars. The process is repeated until the secondary bed is covered with rounds, all straightened by rolling, and lying in contact with one another. With the secondary bed filled in this manner, the cooled rounds will be delivered to the shuffle bars during the continued operation of the process, which then is continuous, maintaining a pack as shown in Fig. 12.

The bar-lifting arms shown in dotted lines in Fig. 10, and serving to raise the rounds from position *A* to position *B*, are attached to a shaft, located as shown, beneath the surface of the primary bed. The shaft is motor driven, and when turned approximately one-half revolution the bar-lifting arms become hidden below the bed surface and another set of arms attached to the same shaft, which will be referred to as "packing arms," are moved to

operating position. The packing arms are illustrated in Fig. 13, and are used to turn flats edgewise and deposit them on the primary-bed section. The slope of the primary bed is made adjustable for reasons readily understood from the operation of the bed, yet to be described.

With the packing arms in operating position, and the slope of the primary bed adjusted to the position shown in Fig. 13, the packing dogs, or abutments, previously hidden below the bed referred to. Sections now delivered to the primary-bed section will slide on the steeper slope to be deposited in a groove as shown at *G*, Fig. 17, for subsequent forward movement, groove by groove as additional bars are delivered from the mill.

It will be apparent that angles and irregular sections can be delivered by the mechanisms described to the secondary-bed section for cooling, while supported in grooves, or while placed in close or spaced formation on a flat bed surface.

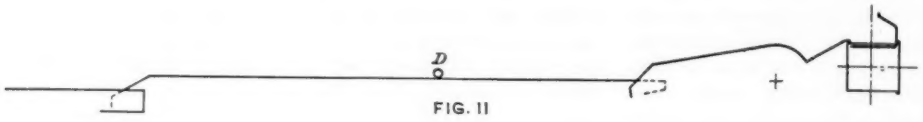

FIG. 11

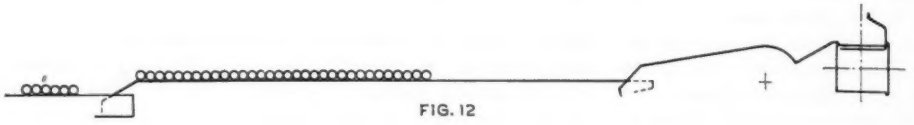

FIG. 12

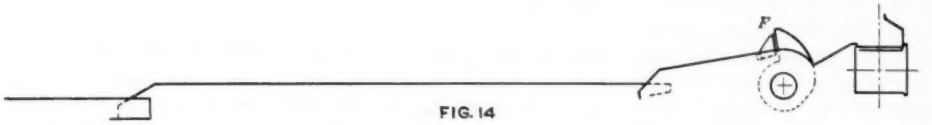

FIG. 14

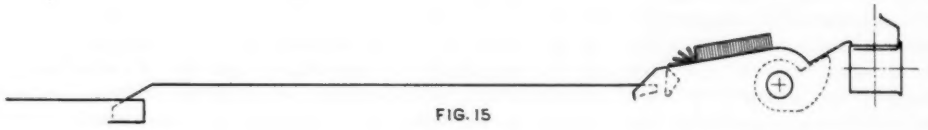

FIG. 15

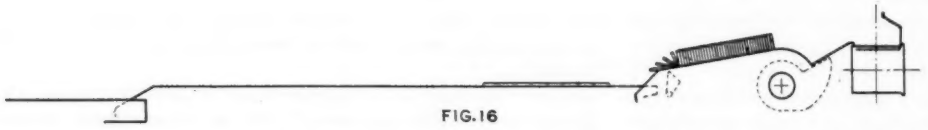

FIG. 16

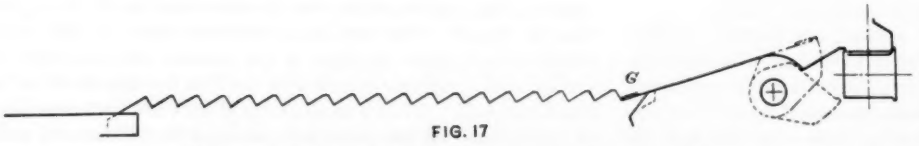

FIG. 17

FIGS. 11, 12, AND 14–17 OPERATION OF COOLING BED

surface, are moved by motor to position also shown in Fig. 13. The bed is then in order for continuous pack-annealing of flats. The first flat delivered to the cooling-bed apron slides to a stop for straightening by impact at position *E*, Fig. 13. It is then moved to position *F*, Fig. 14, and deposited against the dogs by means of the packing arms. Subsequent stages of this packing operation are illustrated in Figs. 15 and 16. Squares may be pack-annealed in a similar manner, except that the use of packing dogs is not then required.

Flats or squares not requiring pack-annealing may be cooled in spaced formation by changing the slope of the primary bed as shown in Fig. 17 and by changing back to the bar-lifting arms first

COLD SHEARING

Beyond the cooling bed is the shearing equipment for cutting the cooled mill products to lengths for shipment. It is frequently the case that one cold-bar shear is unable to keep up with the production of a mill, and merchant mills for this reason are often provided with two shears for dividing the rolled bars into the desired lengths. The conventional way to meet this situation has been to provide a double cooling bed, such as shown in Fig. 1, to divide the mill products between two beds, which in turn deliver to individual shear tables and shears. This can hardly be termed a practical and economical solution to the problem, for several reasons. A cooling bed is an expensive piece of equipment, but can be built for practically unlimited cooling capacity without very materially increasing its cost. The run-in table to the cooling bed, the bar-assembling means following the cooling bed, such as shuffle bars, and the cold run-out table, are all the same, irrespective of bed capacity, for any given length of bed. To increase the capacity of a bed, it is merely necessary to lengthen the carry-over bars of the bed proper and possibly make the operating mechanism for this bed portion somewhat heavier. The double bed must, for this reason, be considered incidental to double shearing and not as a requisite to augment the cooling capacity. Cooling beds are very reliable in service, and it would seem far-fetched to consider one side of a double cooling bed as a necessary spare in case of trouble on the opposite side.

In the layout shown in Fig. 2 there are two shears, but only one cooling bed. Still the two shears have theoretically the same shearing capacity in either case. This is accomplished by spacing the shears from the cooling bed so that the first shear is removed from the bed a distance not less than one-half the bed length. The cooling bed is provided with two cold run-out tables, one for each shear, and the first shear is built so as to permit the cold run-out table for the second shear to run through its frame. Furthermore, a transfer mechanism is provided, as shown in cross-

section in Fig. 10, which serves to lift a set of bars from the run-out table next to the cooling bed, transfer it to above the rollers of the second run-out table, and lower it onto these rollers, all in one operation. This transfer mechanism is made of the same length as the cooling bed, to handle batches of full-length bars.

Referring to Figs. 10 and 2, a group of rolled bars are assembled on the shuffle bars and transferred in the usual manner onto the first cold run-out table. This group of bars is immediately transferred, by the mechanism already referred to, onto the second cold run-out table for conveyance to the second shear. In the meantime, another group of bars is moved onto the first run-out table and conveyed by its rollers to the first shear. Assuming the two shears to be operating at approximately the same speed, it will be apparent that this process can be continued indefinitely, by alternately furnishing groups of bars to the two shears. The distance between the cooling bed and the first shear provides for the necessary timing.

The additional table and transfer equipment necessary with the layout shown in Fig. 2 are decidedly cheaper than the extra cost of a double as compared with a single bed. The shearing capacity in either case is the same. There are other advantages, however, which make the shearing and cooling bed layout shown in Fig. 2 very desirable.

A double cooling bed takes up a great deal more space, and the layout of the mill usually makes it necessary to locate the cooling bed more or less centrally in the mill building, thus dividing the remaining floor space into narrow portions, of little value for storage and handling purposes. With the double shearing arrangement from a single cooling bed, the bed, table, and shear equipment can usually be placed over to one side of the mill building. Not only is considerable floor space conserved in this manner, but the remaining portion is uninterrupted, and for that reason decidedly more useful. Compare Figs. 1 and 2, which both show actual modern installations.

Let us next consider a mill with two cooling beds serving different outlets and handling different classes of products. One bed of such a mill would be comparatively long and narrow for small-sized bars. The outer outlet, delivering heavier products, would require a shorter bed, but wider to obtain sufficient cooling capacity. Taking advantage of this situation, both beds can be made to deliver to the same cold run-out table, as is the case in the mill layout shown in Fig. 3. An additional cold run-out table and transfers, just as specified in the case of the layout shown in Fig. 2, make it possible, and entirely practical, to use two shears for shearing the products from either of the two beds. Since the two outlets are never used at the same time, this arrangement gives the advantage of two double beds with two shears for each, and with a decided saving in cost, mill floor space, and ease of operation.

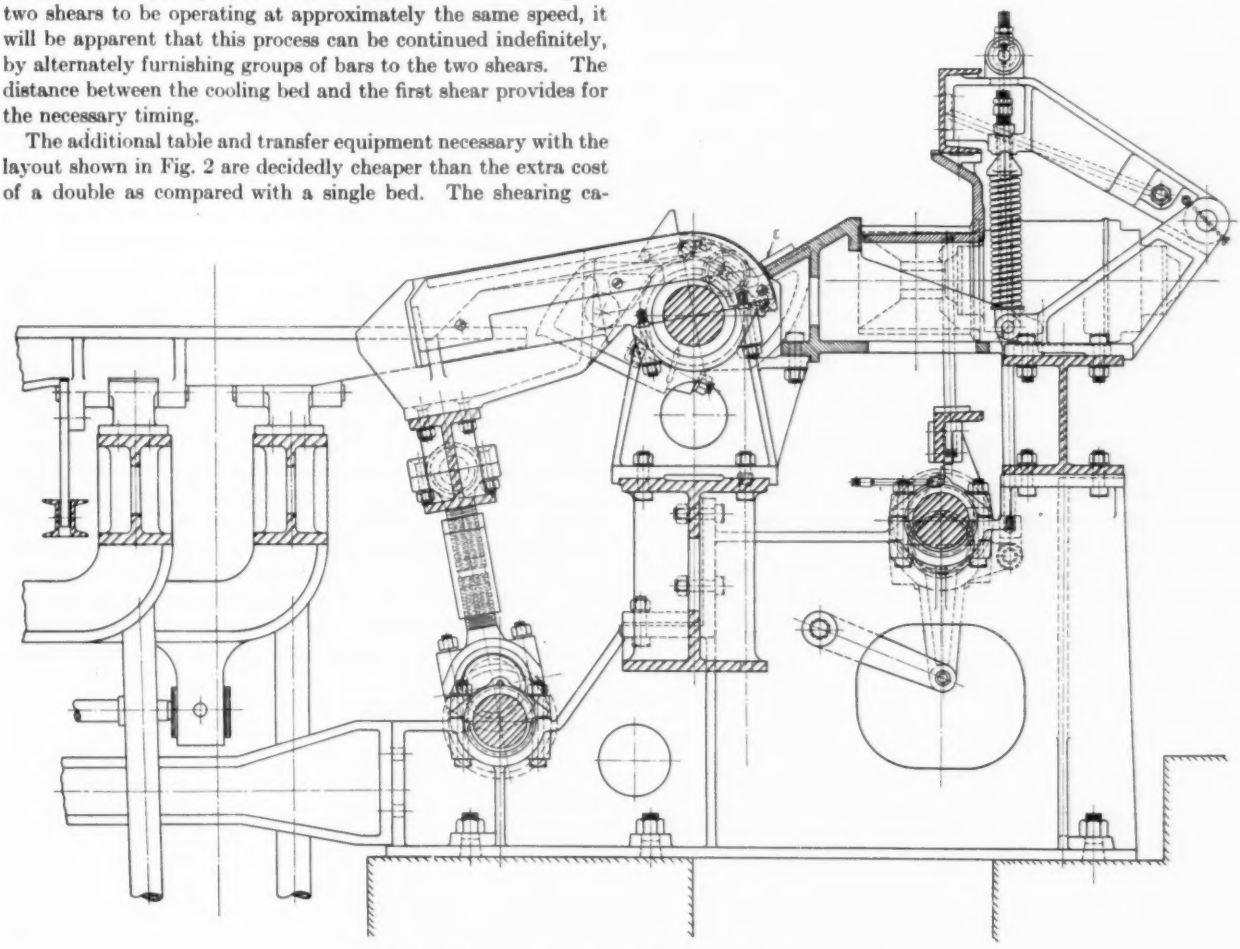

FIG. 13 SHOWING DETAILS OF COOLING-BED MECHANISM

There are no doubt many other recent improvements worthy of note, but some of these must as yet be considered in the development stage. This is the case, for example, with satisfactory equipment for the coiling of merchant bar. Developments in this line are to be expected.

Comparing the merchant mill of today with that built five or more years ago, there is undoubtedly a strong tendency toward labor-saving and high-grade equipment. Quantity of product, once the seemingly all-important factor, is now considered, only as far as consistent with quality, the paramount requirement.

Discussion

S. M. Weckstein.[2] The author has pointed out that attempts have been made with more or less success to substitute roller bearings on the rolls of existing mills. It has been our experience that the rolling requirements of the mills will govern the possibility of making the changeover.

At the plant of the Timken Steel and Tube Company two stands of 22-in. three-high bar mills designed for plain bearings were changed to tapered roller bearings. The necks for the plain bearing rolls were 14 in. in diameter and 14 in. long. For the roller bearings the necks were cut down to 12 in. diameter. The length of neck was retained, as were the 24 in. maximum and 21 in. minimum roll diameters. The housings were machined out for the bottom roll. At the present time these stands can easily be changed over from plain to roller bearings by the use of proper liners. This was demonstrated recently when comparative tests were made on the same rolling practice on plain and roller bearings. These tests showed power savings of $40^1/_2$ to $48^1/_2$ per cent in favor of the roller bearings. The bearings on the pinion stand also were changed over to roller bearings, and the total savings obtained have long since paid for the cost of the changeover.

The same satisfactory results have been obtained on a number of changeovers of 10-in., 12-in., and 16-in. two- and three-high mills.

We have, however, run into a number of cases where it has been impossible to make the changeover due to the rolling loads encountered. In some cases it was impossible, due to the outside diameter of the bearing, to retain the present minimum roll diameter. In other cases it was necessary to change to alloy rolls in order to retain proper neck strength. In still a few other cases the housings were not strong enough to permit of opening up the windows the required amount.

It has been pointed out that in new mills proper provision can be made for the incorporation of roller bearings by an increase in roll diameters. This naturally increases the roll cost and to some extent the mill machinery cost. To offset this initial increase in cost it should be borne in mind that it is safe to figure an average saving of about 30 to 35 per cent in power, and consequently a reduced first cost of the electrical equipment required. In addition the reduced cost of lubrication and maintenance and the reduction in scrap due to positive control of the accuracy of the product must be credited to the roller bearings.

Another important factor which as yet cannot be fully accounted for is the life of the bearings and the resultant cost of bearings per ton of product rolled. At the Timken plant there are two stands of three-high 28-in. mills, two stands of three-high 22-in. mills, three stands of 18-in. two-high mills, one stand of 16-in. three-high, and six stands of 16-in. two-high mills, all equipped with tapered roller bearings. On all of these mills an accurate record is being kept of the number of hours of operation and the number of tons rolled on each individual bearing. For example, in the 28-in. mills where bearings of 16-in. bore 24 in. outside diameter by $12^1/_2$ in. long are used, the maximum tonnage rolled on any one bearing to date is approximately 200,000 tons, equivalent to approximately 5000 hours in service. At the last inspection these bearings were in perfect condition. Similar tonnages have been rolled on the other mills with the bearings in perfect condition.

The question of spares is also important. In 1928, when the Timken company mills were installed, the experience with roller-bearing-equipped merchant mills was limited. Consequently, as a safety measure it was decided to carry on hand a large number of spares. The set-up was to have a complete set of bearings in the mills, a complete set of bearings assembled on the spare rolls ready to go in the mill, and a third set mounted in chucks and ready for assembly on any desired rolls. A study of the record charts giving the tonnage rolled on the bearings shows that only a few of the third set of bearings have ever been used. This is due to the trouble-free operation of the bearings and to the ease of changing bearings on rolls. It is therefore safe to figure on one set of bearings in the mill and one set of spares.

Carburizing With Butane Gas

By C. W. SPICER,[1] TOLEDO, OHIO

The hydrocarbon gases of the paraffin series which are being used for commercial carburizing include methane (natural gas), propane, and butane. These hydrocarbons used without the admixture of air or other gases apparently give up carbon to the steel during certain cracking processes which occur at certain rather sharply defined temperatures and other conditions. Operating conditions which give satisfactory results with one hydrocarbon may not produce satisfactory results with other hydrocarbons. These conditions are not difficult to meet when fully understood.

Well-controlled butane offers: (1) smaller temperature range than commercial solid carburizers; (2) carburizing material at low cost; (3) maximum carburizing rate at temperatures metallurgically and economically advantageous; (4) chemically constant carburizing material; (5) carburizing material requiring no complications, such as admixture of air or other gases; (6) no labor or space within the plant is required for handling or storage of solid carburizer; (7) carburizing process so free from dust and dirt that with proper furnace equipment it may be placed in the regular factory line of manufacture; (8) absolute control of depth and character of case.

The paper gives some details of the author's experiments, certain general observations regarding the physical chemistry and a table of physical constants of the paraffin hydrocarbons, a description of a flowmeter for measuring the flow of carburizing gas to the furnace.

IN GENERAL it may be said that all commercial steel harder than the softest grades is dependent upon its carbon content for the additional hardness, although of course it may have its hardness increased, to some extent, by cold work; also the hardness as well as the strength is effected to some extent by various alloying elements, notably, manganese, chromium, tungsten, nickel, molybdenum, vanadium, etc.

Generally speaking, in spite of the marvelous progress that has been made in steel composition during the last few decades, we still do not know how to make steel commercially that is extremely hard and resistant to abrasion and at the same time tough and ductile. That is to say, steel that is extremely hard is also brittle, and therefore usually not well suited to withstand shocks or flexure.

Steel that is low in carbon is usually comparatively tough and ductile, and is therefore suitable for use where it is subject to shocks. Low-carbon steel may be given a skin of higher carbon which, with suitable heat treatment, will afford a hard and abrasion-resistant surface while the inner part remains tough and shock resistant. This combination furnishes the nearest approximation which we have to a steel which is hard and abrasion resistant on the surface, and at the same time sufficiently tough internally to withstand shock and some flexure without failure, and it therefore finds extensive use in steel machine parts.

The process of adding carbon to the surface portions only of a piece of steel, is known as "carburizing" or "cementizing," or in the vernacular, "case-hardening." It is also well known that the thickness of the hard skin or "case" may be varied at will by the treatment given. In fact, the piece of steel may, if desired, be carburized all the way through, thus changing it from a piece of low-carbon steel to one of high-carbon steel. This method is a very old one. The famous swords of Damascus are believed by some to have owed their superior cutting qualities and sturdy flexibility to steel which had been carburized, although the word "carburized" is of very much more recent origin.

The process was formerly carried out by heating the parts packed in carboniferous material in some kind of heat-resistant boxes. Previous to perhaps twenty years ago the better grades of work were obtained by using charred leather, granulated bone, and similar substances of animal origin. These materials, especially granulated bone, are still used to some extent, but most carburizing is now done by packing in granulated materials consisting mainly of various kinds of charcoal and coke with which are mixed small percentages of chemicals such as barium, calcium, and sodium carbonates. These chemicals are known as "energizers" or "activators," because their presence accelerates the absorption by the steel of carbon from the charcoal-coke source of supply, probably through the intermediary of carbonaceous gases.

During recent years various gases have grown in favor as the source of carbon and gaseous carburizing materials, and methods of application have been the subject of many patents. There are two more or less distinct methods of using gaseous carburizers:

1 Indirect, or converting the carbon into carbon monoxide, which carries the carbon in available form. This method is available wherever the carbon can conveniently be converted into carbon monoxide and is probably more generally available than the following method.

2 Direct, or breaking down the carboniferous compound in the presence of the steel to be carburized, into other compounds containing a less proportion of carbon, thereby releasing nascent carbon directly to the steel without the intermediary carbon monoxide.

The present discussion will be confined to the latter method.

---

[1] Vice-President and Mechanical Engineer, Spicer Mfg. Corp. Mem. A.S.M.E. Mr. Spicer received his mechanical engineering education at Cornell University, with the class of 1904. His work in automotive engineering, especially in connection with universal joints, propeller shafts, and propeller-shaft tubing, is widely known. He is on the A.S.M.E. Standing Committee on Standardization; has served two years as treasurer of S.A.E. Council; has been a member of the S.A.E. Standards Committee since 1912; is chairman of the Sectional Committee on Small Tools and Machine Tool Elements under A.S.A. procedure; and is a member of the A.I.M.E., Am. Electrochem. Soc., and Am. Soc. Steel Treating. In recent years he has done considerable development work along various heat-treating lines, of which the subject of the present paper is one.

Contributed by the Iron and Steel Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Mechanics of Carburization

In dealing with the subject as a whole, it will be advantageous at this point to consider the mechanics of carburization—that is, the method or manner in which the carbon is transferred from the carburizing material to the steel. The most commonly accepted theory regarding solid carburizers seems to be that carbon monoxide (CO) is the intermediary between the carburizer and the steel. Experiments indicate that steel will take up little or no carbon directly from solid carbon in a vacuum—that is, in the absence of gas. Experience seems to prove conclusively that no carbon monoxide, cyanogen (CN), or any other compound of oxygen or nitrogen is essential to satisfactory carburizing with some carburizing materials including butane gas.

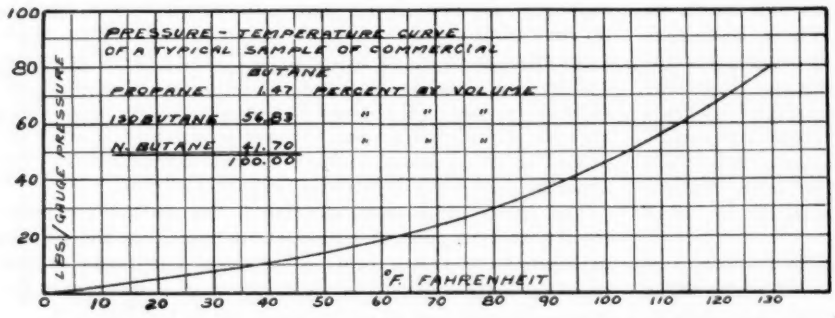

Fig. 1 Pressure-Temperature Curve of a Typical Sample of Commercial Butane

As a theory of the mechanics of carburization of steel, the author submits that the essentials consist of steel in the presence of some substance containing carbon in chemical combination, which combination shall change while in intimate contact with the steel to be carburized and at a temperature or temperatures metallurgically suitable to the steel, into other chemical combination or combinations containing a lesser proportion of carbon and thereby releasing nascent carbon to be absorbed by the steel; provided, that no other element is present which has a greater affinity for the nascent carbon than the steel has at the particular temperature at which the change in combination takes place. Further, that any substance, solid, liquid, or gaseous, that meets the foregoing conditions may be used as a carburizer with greater or less efficiency, but that obviously a vapor or gaseous compound will be the most efficient because of the greater ease with which that portion of vapor or gas in intimate contact with the steel and which has given up its quota of carbon to the steel, and has thereby lost its potency, may be replaced with potent material.

Properties of Butane and Other Hydrocarbons

Butane has long been known as a small-percentage component of natural gas and of crude petroleum, but has not been developed as a generally available commercial fuel until within the last very few years. It is obtained commercially from at least three more or less distinct sources:

a It is a by-product of compression plants at the origin of long-distance natural-gas transmission lines

b It constitutes one of the numerous "light ends" at crude-petroleum distillation plants

c It is a by-product of the petroleum "cracking" still due to the overhydrogenation of small portions of the heavier hydrocarbons.

Butane is transported as a liquid under pressure in suitably constructed tank cars or in smaller pressure containers. The pressure varies with the temperature. Fig. 1 shows this relation for a typical sample of commercial butane. Since butane gas is rapidly assuming a place of commercial importance and since information regarding it is not generally available in the mechanical handbooks, data on butane and closely related hydrocarbons are given in the accompanying Table 1.

Propane is the next lighter hydrocarbon of the paraffin series and is obtained from the same sources as butane. It has for some years been marketed under various trade names, as a gas for kitchen ranges and other heating purposes, where commercial gas mains are not available. Propane may be readily obtained commercially in 100-lb drums as well as in tank cars and may be used as a carburizer quite similar to butane, although to obtain the best results the temperature and rate of gas feed will be somewhat higher than when butane is employed.

These hydrocarbons begin to change or "crack" when the temperature is increased above certain limits, which vary with the hydrocarbon under consideration. The temperatures at which these changes begin in the presence of steel only are approximately as follows:

Methane	1200 F	Propane	860 F
Ethane	840 F	Butane	815 F

While the temperatures given are those at which changes begin to occur, temperature differences continue on up through the working ranges; that is, if methane cracks into certain other hydrocarbons at, say, 1700 F, butane may be expected to produce similar hydrocarbons at some lower temperature, perhaps 1500 to 1600 F. Further, it happens that most of the hydrocarbons obtained by cracking at these temperatures will crack again into other compounds at still higher temperatures, but it also appears that most of the hydrocarbons which are formed within the temperature range metallurgically suitable to the steel, namely, 1500 to 1800 F, do not in general change again under carburizing-furnace conditions until a temperature of 2000 F or more has been reached, which of course is much too high for the steel from a metallurgical point of view.

Further, it appears that in carburizing, as in many chemical operations, the desired action is much more effective when certain of the hydrocarbon's constituents are in a nascent condition. This, considered with previous statements and some which are to follow, suggests the reason why each hydrocarbon has its own particular temperature range and rate of gas feed at which it is most effective, and outside of which the results may be far from satisfactory.

It may be noted here also that these changes may produce hydrocarbons which are much more complicated in their atomic structure than the original gas. For instance, imagine the author's surprise during his carburizing experiments to find that while he had butane entering one end of the retort, he had coal-tar vapors mixed with naphthalene (from which moth balls are made) and probably other less easily detected substances issuing in substantial quantities from the other end of the retort in which carburizing was supposed to be taking place and not the manufacture of drugs and road materials. Incidentally it may also be noted that, under the conditions where tar was given off, it formed a coating on the work being carburized which, when the temperature was further increased, seemed to dry out, leaving a coke-like coating which effectively prevented carbon penetration at any temperature. This coke-like substance adhered so tenaciously to the surface that nothing less drastic than a severe sand blast would remove it.

Specific gravity of gaseous pentanes and hexane, specific heats of gases, and volume of air required for combustion computed.
Limits of inflammability from U. S. Bureau of Mines Bulletin No. 279.
All other data based on figures from International Critical Tables and from paper by Dana, Jenkins, Burdick, and Timm, *Refrig. Eng.*, vol. 12 (1936), p. 387.
* Inches of mercury vacuum.

The various hydrocarbon gases in Table 1 may in general be transformed into other similar classes of hydrocarbons by suitable manipulation of temperature, pressure, rate at which the gas is fed through the retort, length of time that the gas is exposed to any specific temperature, the material of which the retort is composed (steel, copper, quartz, glass, etc.), and probably some other conditions.

In view of all the possibilities, it is not strange that experimenters with butane for carburizing have experienced much difficulty when trying to use it according to methods previously developed for methane (natural gas) or solid carburizers.

Experiments With Butane in Carburizing

In beginning his butane carburizing experiments the author acted on the advice of a well-known builder of carburizing furnaces, namely, that the proper carburizing mixture to use would be 18 per cent butane and 82 per cent air. This recommendation was evidently made in the belief that the presence of a gas containing oxygen is essential to successful carburizing. Considerable care was taken to obtain exactly the specified mixture of air with the 48 cu ft of butane gas per hour which the rotary-type furnace to be used in the experiments was supposed to require. Again imagine the author's surprise after taking extreme care to get the proper quantity of the correct mixture, to find after only half an hour at heat that the end of the heavy nichrome tube, through which the mixture was introduced into the retort, as well as the control thermocouple, were completely melted away! And worse still, the batch of material to be carburized, consisting of about 8000 small steel bushings, was welded together and rolling around in chunks the size of a man's head! If one's foresight were only as good as one's hindsight, much trouble would be saved in experimental work. An 18 per cent butane mixture is still twice too rich to be a combustible one. Obviously, however, when entering a hot furnace the oxygen promptly combined by partial combustion with the carbon and hydrogen present to form, among other things, the carbon monoxide (CO) which the author's adviser apparently desired. Both the author and his adviser, however, failed to recognize that even the partial combustion of 48 cu ft per hr of butane gas containing approximately 3200 Btu per cu ft would liberate enough heat to ruin the inside of an already hot furnace, including its contents.

Naturally the author promptly decided that, if butane was to be used, some other method than the one advised would be necessary. After a little further study he decided to see what would happen if he used butane without any admixture of air. By blind luck (as he now knows) the first batch of work tried with the raw gas turned out an excellent eutectoid case approximately 0.040 in. thick within four hours at heat.

Several experimental heats were run at that time, all of which were very successful, and at that stage carburizing with butane, as it seemed to the author, was extremely simple. These experiments were conducted using both butane and propane from 100-lb drums.

Some months later an installation for using butane gas as a principal heating fuel was completed, and that gas was available for production carburizing. What a surprise was in store when the use of butane was started in regular production! Instead of being 99 per cent perfect as anticipated, the results were very unsatisfactory because the time required to obtain a suitable depth of case was much too long, and even when the depth was sufficient, the character of the case was not satisfactory.

Several impromptu modifications were tried without satisfactory results, and the entire carburizing department then went back to the use of solid carburizer until the discrepancies between experimental and commercial practice could be ironed out. It was at this point that the author found it necessary to add substantially to his knowledge of hydrocarbons and their action under heat. A study of some late literature apply-

ing primarily to the cracking of the heavier hydrocarbons to produce gasoline brought out many facts, some of which have been previously noted, especially the fact that different hydrocarbons may crack into similar products at suitably different temperatures. It was known that methane (natural gas) was being successfully used at the same temperatures that are commonly used for solid carburizing material, namely, 1700 to 1750 F, and it seemed that butane might be successful at some lower temperature.

The fact also developed at this time that the original experiments had been conducted at temperatures in the vicinity of 1600 F for metallurgical reasons and not to favor the carburizer. In production the gas was put into service at about 1700 to 1750 F. Dropping the temperature to 1600 F immediately gave better results, but before again attempting the use of butane in regular production, it was decided to explore the entire possible range, because 1700 F seemed too high for the butane and about 1500 F is well established as a minimum limit at which steel will take up carbon at a commercially feasible rate. It also seemed obvious at this time that the rate of gas flow would probably have an important influence upon results.

Results Obtained in Experiments

Briefly, the results are as follows:

At 1450 F large quantities of tar, naphthalene, etc. were obtained with no case visible after 4 hr at heat

At 1500 F there was less tar and other undesired products and a trace of low-carbon case after 4 hr at heat

At 1550 F there was very little of tar and undesired products

At 1575 F a satisfactory case on moderately heavy work was obtained in 7½ hr with absence of undesirables

At 1600 F the time was cut to 5 hr for 0.035-in. to 0.040-in. case as indicated by the color test

At 1625 F to 1670 F the corresponding case was obtained in 4 hr

At 1700 F the time was increased to 5 hr, and as the temperature increased above that point the carburizing time increased rapidly with a similar supply of carburizing gas.

The field above 1700 F was not exhaustively investigated with larger gas flow for three reasons:

1 Grain structure of the material is less satisfactory
2 Larger gas flow would be less economical
3 Depreciation of the furnace and equipment would be increased.

For a rotary type of furnace which has a capacity from 500 to 800 lb of work per charge, it has been found that a butane-gas flow of 15 cu ft per hr for the first half of the carburizing period and 8 to 10 cu ft per hr for the last half of the period, gives satisfactory results as to quality and speed instead of the 48 cu ft per hr previously mentioned.[2]

[2] A convenient and inexpensive flowmeter may easily be made for each furnace in the manner illustrated in Fig. 2. A nozzle with reduced area is placed in the gas-flow line and a standard U-gage from any instrument maker with a 10-in. range is attached to the flow line on either side of the nozzle so that the U-gage measures directly in inches of water the pressure drop through the nozzle. Suitable calibration makes it easy to read in cubic feet per hour for a given size of nozzle. Exact calibration will vary not only with the diameter of the nozzle aperture but with its length, smoothness of finish, angle and freedom from burrs at the ends, etc. A nozzle of the dimensions shown in the sketch, with plain drilled hole and no especial care given to finish, will pass approximately the following quantities at atmospheric pressure from an initial pressure of 8 in. of water, viz.:

6 in. water pressure drop as shown by U-gage, 23 cu ft per hr; 4 in. drop, 19 cu ft; 2½ in. drop, 15 cu ft; 1 in. drop, 9 cu ft; ½ in. drop, 6 cu ft.

It appears that the rate of increase of thickness of the case, when butane or equally potent carburizer is used, is principally dependent upon the ability of the steel to absorb and diffuse the carbon at the operating temperature. A higher carbon content than is usually desired is easily and quickly obtained near the surface of the steel, but it seems necessary to allow a rather specific length of time for the carbon to penetrate into the steel and for the high carbon content near the surface to properly diffuse.

This is the reason for the reduced rate of gas flow during the latter part of the process time; i.e., for practical reasons of speeding up the operation, the gas during the first part of the operation is fed as fast as the steel will take up the carbon, resulting in too high a carbon content near the surface, but more rapid penetration.

When a sufficient total amount of carbon has been added to finally give the desired concentration and depth of case, the supply of carburizing gas must be reduced to an amount which will just maintain a satisfactory carbon concentration near the surface of the steel during the time which is necessary for the surplus carbon near the surface to become properly diffused. Under some conditions, if the carburizing retort is gas tight, the supply of carburizing gas may be entirely cut off during the latter part of the diffusion period.

The author is frequently asked about the amount of free carbon or lampblack present. There is only a small amount of this material present if the proper gas flow is used. In the furnace just mentioned about a pint of loose, flocculent lampblack may be present at the completion of the run, which for this quantity of charge means that the work is comparatively clean and that there is much less dust and dirt than from a corresponding batch using solid carburizing material.

The current prices of liquid butane in carload lots in the industrial district between Chicago and New York inclusive, range from 6 to 9 cents per gallon, delivered on the customer's siding. The price varies with the freight rate from shipping point to customer's siding, and to some extent with a sliding price scale depending upon the customer's monthly requirements. One gallon of liquid butane is equal to about 32 cu ft of butane gas at atmospheric pressure; thus for a 4-hr heat of the size described above about a gallon and a quarter or not more than 10 cents worth of butane will be used. For corresponding results with solid commercial carburizers at the present market price of approximately $50 per ton, about 50 to 55 cents' worth of new solid carburizing material will be required. Thus the cost of butane as a carburizing material is only about one-fifth that of solid carburizer at present market prices. Labor costs are also much in favor of the gas. Where a deep case is required, solid carburizer loses its effectiveness so that the work may have to be repacked with fresh carburizer one or more times to obtain the required depth. With gas carburizers conditions are at all times under positive control, and the process may be continued without interruption until the desired depth of case is obtained.

Conclusion

From the foregoing it appears that:

A quarter-inch needle valve adds greatly to the convenience and accuracy of regulation.

It is further suggested that unless an unusually sensitive and accurate pressure control has been placed in the main gas-supply line, the carburizing-gas feed be taken from the high-pressure side of the main reducing valve as the pressure variations due to large units going on and off the line will probably be less pronounced at that point and the proposed quarter-inch needle valve will easily handle the higher pressure, and a steadier flow of carburizing gas will result.

1 The possible temperature range with butane is smaller than with the usual commercial solid carburizers.

2 The rate of flow of carburizing gas should be controlled within suitable limits for best results (see Fig. 2).

3 Both temperatures and rate of feed have sufficiently wide ranges to be easily met commercially as well as experimentally.

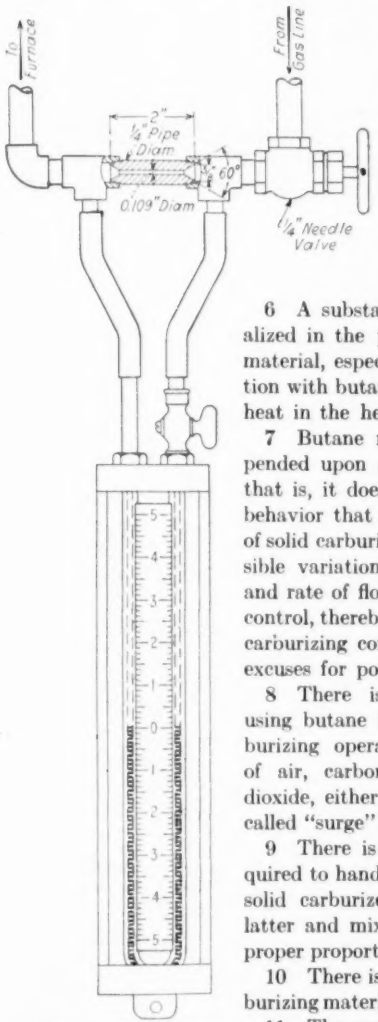

FIG. 2 FLOWMETER

4 When so controlled, butane gas offers an exceedingly satisfactory carburizing material at low cost.

5 At the maximum carburizing rate, the temperatures are advantageous both metallurgically and economically.

6 A substantial saving may be realized in the purchase of carburizing material, especially if used in connection with butane as a general source of heat in the heat-treating department.

7 Butane may be practically depended upon as chemically constant, that is, it does not exhibit the erratic behavior that always annoys the user of solid carburizer. The principal possible variations, namely, temperature and rate of flow, are within the user's control, thereby permanently removing carburizing compound from the list of excuses for poor results.

8 There is no advantage when using butane in complicating the carburizing operation by the admixture of air, carbon monoxide, or carbon dioxide, either continuously or by so-called "surge" methods.[3]

9 There is no labor or space required to handle and store new or old solid carburizer, nor to reclaim the latter and mix it with new material in proper proportions.

10 There is no deterioration of carburizing material in storage.

11 The carburizing department, in general, is much cleaner when a gas carburizer is used. In fact, the carburizing, quenching, and rehardening machines may now be placed in the regular line of manufacture if desired instead of being segregated as usual, thus saving interplant transportation.

12 By suitable control of temperature and gas flow the depth, type, and character of case are in absolute control at all times. A properly graduated case is easily obtained, and the surface may be hypereutectoid, eutectoid, or hypoeutectoid.

13 Under proper conditions the penetration of carbon is as rapid as by any other commercial process known to the author, and because there is no exhaustion of the carburizing material, the rate of penetration may be maintained at maximum.

[3] The carburizing gas is simply flowed through the work at the proper rate after the work has reached the operating temperature. The formation of slight scale caused by oxygen present in the furnace while heating up may be avoided by flushing the air out of the furnace immediately after loading. This may be done by allowing the butane to flow into the retort until it may be lighted and burns with a bright yellow flame at the vent, and then closing the retort until the operating heat has been attained.

Appendix

The facts brought out in this paper raise some interesting questions which may be definitely answered only by further research. As noted in the paper, methane begins to change or crack at a temperature of about 1200 F, whereas ethane, propane, and butane begin to crack at temperatures roughly 350 deg lower. Methane apparently is more stable at all temperatures below 2000 F than are the other hydrocarbons mentioned. Furthermore, methane is one of the important products resulting from the changes which occur in the other hydrocarbons mentioned at temperatures around 1600 to 1700 F. It is claimed by some authorities that the methane does not radically change to a great extent until temperatures upward of 2000 F are reached. It therefore seems probable that the change from ethane, propane, or butane to methane, which contains a much smaller percentage of carbon, is the real source of the nascent carbon required for carburization of the steel with these gases when no oxygen is used. Apparently unless the supply of carburizing gas is greatly increased so that the time during which the gas is exposed to the heat is reduced, the change to methane is so nearly complete that only a comparatively small amount of nascent carbon is available by the time the gas has attained temperatures upward of 1700 F.

These inferences are given weight by the fact that although artificial coal gas may contain as high as 50 per cent of methane, it is not always a satisfactory carburizing medium unless the carbon combination has been changed from a hydride to an oxide, carbon monoxide apparently being sufficiently unstable within the carburizing temperature range that it gives up its carbon to the steel, thereby changing to CO_2.

Another question which naturally arises relates to the successful use of natural gas as a carburizing means without the addition of oxygen. In the case of at least one large user of natural gas for carburizing without oxygen, it is known that the natural gas from the West Virginia field from which that company receives its supply contains from 17 to 33 per cent of ethane, which in its behavior under heat appears to be much nearer the butane than the methane range; also that this gas is successful as a carburizing medium at temperatures from 75 to 100 deg higher than butane under other similar conditions. This temperature difference might be expected theoretically between butane and ethane (the author has had no experience with the use of ethane only). Furthermore, the Btu value has apparently little or no relation to the carburizing value.

In view of the foregoing, the question naturally arises as to whether the methane content of the natural gas is in fact useful as a carburizing material when used without the admixture of oxygen or whether the carburizing is the result of the other portions of the gas, principally ethane in the case mentioned, breaking down into methane and thereby liberating nascent carbon. If this is so, the methane might add to the efficiency of the ethane by increasing the volume of gas passing the work and adding to the turbulence of the mixture and thereby causing more rapid change of those portions of the gas in immediate contact with the steel.

These questions are offered as being possible logical inferences from the known facts and as suggestions for further interesting and valuable research work.

Discussion

R. J. Cowan.[4] The paper describes an interesting series of practical experiments and records some important results. It would have been well to have mentioned that in addition to carburization by means of carbon monoxide (CO), carburization, by means of methane (CH_4) or other hydrocarbon, is commonly recognized, that each of these gases produce a characteristic type of case, and that by combining the action of the two a wide variety of case types can be produced when the process is under accurate control. As it stands, the paper is an excellent contribution to one phase of the subject and calls attention to certain limitations that may well be considered.

The fact that the case depth dropped off when the temperature was raised beyond a certain point is in line with some work we have done using propane only for carburizing. We found that we had less case at 1750 F than at 1650 F, although the same time at the higher temperature should have produced a much deeper case.

We have had no experience with the addition of air to these reactions, for, in line with the experiment described by the author, we too were suspicious of partial combustion effects. For this reason in the process of continuous gas carburizing, referred to by the author, we use flue gas instead of air, and since this flue gas contains about 10 per cent carbon dioxide (CO_2), we are able to bring about a reaction whereby nascent carbon monoxide (CO) is produced, which makes it possible to regulate both the methane and the carbon-monoxide carburizing by properly proportioning the hydrocarbon and flue gases used.

It has been our experience that carbon-monoxide carburizing as described produces a case that is characterized by rapid penetration and excellent diffusion between case and core, and that when properly coupled with hydrocarbon, carburization will overcome the tendency toward slow reaction rates at the higher temperatures that is encountered when using propane or butane alone.

The author calls attention in a very interesting way to the many decomposition products formed when a hydrocarbon gas is heated. Our work has confirmed the importance of this observation and emphasized the effect of alloys on these reactions. Various oils and tars are produced in the presence of certain metals, but not in the presence of others. In the presence of nickel, methane begins to break down at a temperature of about 725 F, and the effect is marked in iron-nickel alloys.

European Supplement to Progress Report of the Iron and Steel Division, 1931

By W. TRINKS,[1] PITTSBURGH, PA.

EVEN though a man might visit the European steel works regularly every summer, he would not be able to see all that is new, because it is physically impossible to cover the whole territory in one summer. And if each plant is visited only once every three years, what is noted as an innovation on the occasion of a visit may be almost three years old—and still be new to the visitor. For that reason the following report is to be accepted with caution, but it is based upon the observations of the writer.

About two years ago a large tube mill in Germany adopted a phenol-formaldehyde condensation product (similar to Bakelite) for rustproofing pipes. The material had the disadvantage of having to be baked, which was very inconvenient for welded or screwed joints. The material in question has been superseded by chlorinated rubber, which is dissolved in benzol. It is brushed (by a machine) on the pipe, both inside and outside. The coating protects the pipe against acids and alkalis. The process will be open for licensing in the United States after the patent situation has been cleared. United States patents on a similar process are owned by an American company.

The same tube company has perfected its process for extruding seamless tubes. The process is a few years old, but troubles with the material of the dies and plungers have prevented its commercial use. These troubles have now been largely overcome, and a die now makes 500 tubes. The plunger (internal die) lasts through the extrusion of 900 tubes. A tube $2^1/_4$ in. o.d., 20 ft. long, is extruded in 2 sec. At present the tubes are reheated before they are rolled down continuously (in reducing or "sinking" mills) to $^3/_8$-in. gas pipe. A new press is being installed, however, to extrude 4-in. tubes, which will be rolled down without reheating.

The same condition (with regard to relative newness) applies to the expanding mill which uses a tension mandrel. It is several years old, but high-class tubes of absolutely uniform wall thickness have been made only recently. Tubes are expanded up to 24 in. in diameter, beginning with a 13-in. tube blank. The first pass expands from 13 in. to 18 in., and the second pass from 18 in. to 24 in.

In the production of seamless tubes, the quality of the steel heretofore has had to be very good. As a matter of fact, people bought seamless tubes because the very existence of a seamless tube was a guarantee of good material. Apparently, the piercing mill accentuates initially existing flaws in the steel. To circumvent this troublesome dependence upon the material, the tube mill at Anzin (near Valencienes, France) has built a large press in which the ingot is pierced by a plunger before it is cross-rolled. What used to be the piercing mill has now become an expanding mill.

The United Steel Works has improved the Roeckner process of rolling seamless drums up to 22 ft. in length and 44 in. in diameter, in thicknesses up to 3 in. or even more. The smallest possible wall thickness is at present $1^3/_{16}$ in., because of the difficulty of keeping thin tubes hot while rolling. Heretofore the drums had a deep grooving (from the cutting-in rolls) on the inside. This grooving is now removed by a second pass. An innovation in the making of superior strength drums consists in boring out a solid ingot, reheating, and rolling on the Roeckner mill. For such drums prices up to $170 per ton have been paid.

One of the most interesting developments is the automatic welding of wide-flanged beams by automatic machinery. The flanges have nosepieces between which the web is inserted. Carbon electrodes melt part of the nosepieces, fastening the flanges to the web partly by resistance welding and partly by fusion welding. The plan is to roll medium-sized girders (up to 12 in. by 12 in., for instance) and to weld the larger ones.

While these developments are outstanding and spectacular, much detail progress has been made and previously mentioned processes have been placed on a commercial basis.

For example, the method of blowing blast-furnace dust back into the furnace at a good distance below the stock line, by means of compressed gas, may be cited. This process is over two years old, but has proved out very well in practice and is now commercially perfect.

Operation of the five valves of a blast furnace is slow. These valves are the valves for gas, for air, the snort valve, the cold blast, and the hot blast. A pneumatic control has been introduced in which a fraction of the turn of a handwheel causes these valves to move automatically in the right sequence and without loss of time. This invention, as most of those previously mentioned, is a few years old, but the original designs were a bewildering maze of pipes; and it is only within the last year that simplifications have been effected which make the control useful.

In blooming-mill practice, attention is being paid to the possibility of bringing the ingot to the mill, either little end first (as we always do) or big end first. While the reasons are purely metallurgical, the means for accomplishing the desired end is purely mechanical. The ingot tilter can tilt forward, as is usual with us, or backward, away from the mill. In the latter case, the tilter is turned through 180 deg. and presents an unbroken roller table all the way to the mill. The thought is good, but the scheme is not perfect, because we should always enter the ingot into the mill small end first, and turn it after the first two squaring passes.

A process in which the mechanical engineer is interested only by furnishing the equipment is a method of regaining sulphuric acid from pickling tanks by crystallizing out the iron sulphate. This desirable separation is accomplished by two-stage cooling and stirring. In the low-temperature stage, brine is circulated (which fact necessitates the use of a refrigeration machine). The iron sulphate crystallizes like granulated sugar. The finished mass is emptied on a chromium-iron sieve through which the acid percolates and upon which the sulphate is retained. This method should help to prevent the dumping of sulphuric acid and iron sulphate into our rivers.

While we pride ourselves about multi-pass continuous mills with horizontal and vertical rolls, we must admit that a mill has been developed in Germany which, to use a slang expression, goes us one better. The housings which carry the vertical rolls rest on slides which are inclined at 45 deg. with the horizontal. A screw adjustment slides the housings on these inclines. In consequence, corresponding passes in the vertical and horizontal rolls are brought into correct alignment by a single adjustment. The

---

[1] Professor of Mechanical Engineering, Carnegie Institute of Technology. Mem. A.S.M.E. Professor Trinks was born in 1874 in Berlin, Germany. He was educated at Charlottenburg, being graduated in 1897 with the degree of M.E. with honors. From 1902 to 1905 he was chief engineer of the William Tod Company, Youngstown, Ohio, and since then has been with Carnegie Institute, serving also as consulting engineer with Mesta Machine Company, Jones & Laughlin Steel Company, and Libbey-Owens-Ford Glass Company. He is the author of "Governors and Governing of Prime Movers," "Industrial Furnaces," Vols. 1 and 2, "Roll-Pass Design," etc.

Contributed by the Iron and Steel Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

motors for driving the vertical rolls are located on top of the housings, which consist of four columns. Motor and drive can be swung out of the way very quickly for changing rolls.

The foregoing instances of European progress in the iron and steel industry have been mentioned because they are representative or outstanding. They do not by any means include all of the developments that have taken place in recent years. If there are any questions regarding other developments or in regard to the details of the processes that have been mentioned, the writer will be glad to answer them if possible.

Discussion

A. G. Witting.[2] Professor Trinks has given some extremely interesting information about the progress in rolling-mill design that he found during his visit to steel works in Europe. One could not excape noticing an acknowledgment of superiority for the engineers on the other side. Consequently, when mention was made of the automatic reversal, in a set sequence of the various operating valves, on a hot-blast valve which here in America invariably is reversed by hand, contrasting it with our automatic control for open-hearth furnaces, which according to German opinion just as well can be attended to by the furnace operator, one necessarily got the impression that we, in both instances, were on the wrong track.

The writer takes the liberty of disagreeing with Professor Trinks. Nowadays the temperature of the hot blast for a blast furnace is automatically maintained, with practically no variation after the control has once been set. How this temperature in the air delivered to the furnace is maintained or how it is derived does not matter to the furnace. Furthermore, with a complete automatic control, even if reversals were done automatically, taking the impulse from the stove-stack temperature, it would always be necessary to maintain a stove tender, if for nothing else than to watch that the automatic control is functioning. If this man occasionally is occupied in reversing the stove valves or is just looking on while they are reversed automatically, the result will be practically the same, and there is very little justification for the expense involved by an automatic contraption performing this work.

Entirely different conditions prevail, in the writer's opinion, for an open-hearth furnace. The adoption of automatic control for regulating combustion is a relatively new development and has not yet passed through the stage of experimentation. It is believed, nevertheless, that what has been tried has given good results, particularly balanced draft control. We completed a new open-hearth plant last spring. There has been obtained a remarkably low fuel consumption, using producer gas as exclusive fuel—50 to 75 lb. of coal per ton of steel less than previous record figures. While several factors contribute to this result, it may be said that the balanced draft control has an important bearing on it. Combustion is carried on under continuously changing conditions. We start with a cooler furnace filled with cold scrap; we want to bring it back to the proper temperature and melt the charge as quickly as possible, giving the furnace all the fuel that efficiently can be burned. But at the end of the heat the furnace cannot receive more fuel than is necessary to replace radiation losses. Another factor contributing to the irregularity of waste-gas production is the furnace boil—i.e., the development of CO_2 and CO gases in the bath itself.

If there is not maintained an equilibrium in the furnace between the gases (fuel and air) brought to the furnace and the gases removed from the furnace by stack draft or, better, by an exhaust fan, there is bound to be a loss of fuel. If there is a plus pressure in the furnace room, combustible gases will leak out around the doors; if there is a minus pressure, cold air will leak in. In either case a loss in fuel efficiency results. To judge these conditions, to constantly watch them and to constantly regulate the draft, is too much to be expected of the furnace operator, who has other duties to perform. Hence, the actual value of automatic control that at all times tries to maintain a neutral pressure in the furnace room.

Professor Trinks indicated that in Germany the furnaces have ports and checker chambers encased in plate work to prevent leakage. We do the same; we also insulate the checkers and flue to reduce radiation losses. But with the necessity of large furnace doors that have to be moved often and quickly it is not possible to make them tight.

It also may be pointed out that while flow meters that tell the operator the volume of gas and air going to the furnace may be of a distinct help to the operator in regulating and maintaining the proper combustion ratio, such meters are applicable only to coke-oven, blast-furnace, or natural gas, but not to producer gas. Furthermore, while they will undoubtedly be of great assistance for an alert operator to prevent waste of fuel, they will not tell anything about the leakage from or into the furnace room.

Much more could be added on the advantage of automatic open-hearth control, but it is believed that enough has been advanced to warrant the contention that automatic regulation is more important for open-hearth furnaces than for hot-blast stoves and that in that respect we apparently are more up-to-date than the European steel-works engineers.

John H. Hitchcock.[3] Professor Trinks has mentioned that, in the Roeckner process of rolling seamless drums, rolls are used both inside and outside the drum. The writer would like to ask how such rolls are shaped, and whether they are placed with their axes parallel to the axis of the drum.

H. W. Smith.[4] Professor Trinks states that a tube of $2^1/_4$ in. o.d. and 20 ft. long is extruded in 2 sec. The writer would like to know how many tubes could be made in eight hours.

Effect of Reradiation on Heat Transmission in Furnaces and Through Openings

By H. C. HOTTEL,[1] CAMBRIDGE, MASS., and J. D. KELLER,[2] PITTSBURGH, PA.

In heat transmission by radiation, the reradiation of heat from adjacent surfaces has been a perplexing question. Radiation of heat through openings in furnace walls, radiation in electric furnaces having heating elements under the roof only, and radiation in some types of oil stills from muffles on the floor to the tubes under the roof are all cases in point. In this paper accurate methods of calculation are developed, and curves are presented from which the reradiation and total radiation factors can be read at a glance, for various shapes and proportions of radiating surfaces or openings. Incidental to the chief results, two methods of solving integral equations are presented. The theoretically developed values are checked and substantiated by actual test measurements.

MUCH excellent work has been done on heat transmission by radiation between surfaces of various shapes. This appears to have been limited, however, to direct radiation between two surfaces, each assumed to be at constant temperature throughout. Two distinct problems have called for attention, which involve not only direct radiation but also reradiation of heat from adjacent surfaces the temperature of which is not constant throughout. These two problems are (1) the radiation of heat from electric resistors under the roof of a furnace to the cold charge on the hearth or from a silicon-carbide muffle at the bottom of an oil still to the oil-containing tubes at the top and (2) the radiation of heat through openings in furnace walls. The first problem has to do with heat transfer within the furnace or still, and hence with heating capacity. Radiation through openings, on the other hand, is usually thought of as involving fuel economy only, as affected by loss of heat through doors and burner openings and also through cracks in the furnace walls. A more important form of this second problem, however, relating to furnace capacity and uniformity of heating, also has to do with useful heat transfer within the furnace itself, by radiation through heat ports or perforations in arches or muffles.

The second problem was solved about five years ago (1)[3] by approximate methods which gave results in most cases within 1 per cent of those obtained by the accurate methods of the present paper, for round openings, but which could not well be applied to other shapes of opening.

Mathematically, the two problems are identical; for the resistors or muffle, in the first problem, or the interior of the furnace, in the second, as the radiator, and the cold charge or tubes, in the first problem, or the surfaces of the exterior surroundings, in the second problem, as the receiver, can both be replaced by flat plane surfaces, as will be shown. The problem then involves finding the radiation between two opposite parallel plane ends of a hollow geometrical figure, such as a cylinder or a rectangular prism, taking account, however, not only of the direct radiation between the two end surfaces but also of the heat which is radiated from one end surface to the connecting sidewalls, absorbed, and reradiated by them to the other end (see Figs. 1 and 3).

The exact solution of the problem requires far more time than engineers can afford to spend on it. The object of this paper is, first, to make available for engineering use the results of accurate methods of solution, in the form of charts from which the radiation factors applying to various shapes and proportions of furnace chambers or of openings can be read at a glance, and at the same time to illustrate methods of solving integral equations, such as appear in this problem, in the hope that they may be more widely utilized for the solution of other more important engineering problems which involve such equations and which are as yet unsolved.

The factors derived mathematically have been checked experimentally.

1 Results and Methods of Using Factors

Radiation out of a hollow space such as a furnace interior, when the opening is small compared to the interior dimensions, is "black body" radiation; that is to say, it is equivalent to heat transfer between surfaces which absorb all of the heat that is radiated to them, and reflect none whatsoever, and which, conversely, radiate the greatest amount of heat which it is possible for any surface at that temperature to radiate. For radiation between solid surfaces within the furnace, the radiation is somewhat less than that of the black body; usually about 90 per cent of the latter, for most surfaces found in practice.

As far as concerns radiation through an opening, for reasons explained later the furnace interior can be regarded as equivalent to a flat diaphragm having the same temperature, and located at the inner edge of the opening, as 1–2–3 in Fig. 1; and for radiation between solid surfaces this is self-evidently the case. If this equivalent diaphragm were fully exposed—that is, if all points on the surface could radiate unobstructedly through a full hemisphere, or solid angle of 2π—the amount of heat radiated, according to the well-known "fourth power" or Stefan-Boltzmann law, would be:

$$Q_{\text{Btu per hr}} = 0.172A\left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4\right] \quad [1]$$

for radiation from an area of A sq ft at T_1 deg F abs temp to surroundings at T_2 deg F abs.

The side walls, however, intercept part of the radiation, and although they reradiate a fraction of it, the amount of heat radiated is always less than that from freely exposed surfaces. Equation [1] must therefore be multiplied by a factor which is always less than unity and which depends on the shape of the surfaces

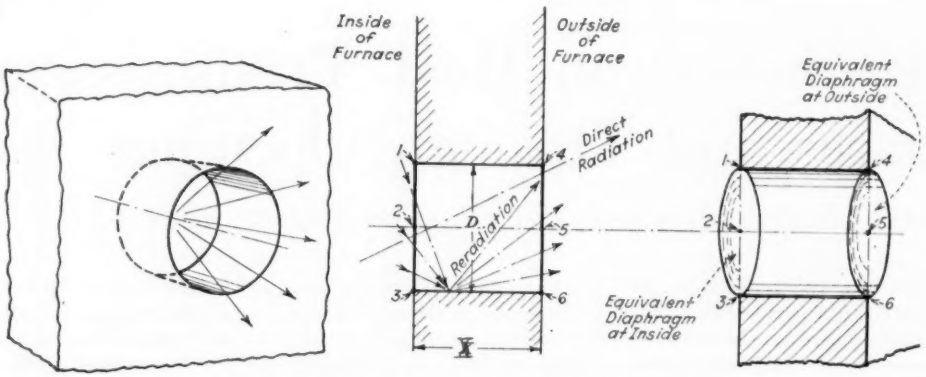

FIG. 1 OPENING IN WALL AND EQUIVALENT DIAPHRAGMS

and on the ratio of their width or diameter to the distance between them. The curves of Fig. 2, embodying results obtained by the methods explained in sections 2 to 6, give values of the total radiation factor for hollow spaces of uniform cross-section and surfaces of four different shapes—namely, the circular, the square, the rectangle of 2-to-1 ratio of sides, and the very long strip (corresponding to a long slot, in the second problem). The abscissa is the ratio of the diameter or least width of the end surfaces (D, Fig. 1) to the distance between them (X, Fig. 1).

The values shown by Fig. 2 are based on heat transfer by radiation only. In any hollow space (except in a vacuum) there is additional heat transfer to the sides of the space by convection of hot gases or air, and this additional heat is also reradiated to the colder end. Tests described in section 8 show that in round openings with axis horizontal the increase due to convection varies from 4 per cent in openings of which the diameter is one-half the wall thickness to 7 per cent in openings of diameter equal to the wall thickness, while in rectangular openings the increase in the former case is about 9 per cent (see section 8).

The method of using these factors will become clear from the following examples.

Example 1. The charging door of a skelp-heating furnace is 7 ft 0 in. wide, with an average height of 9 in., and is open at all times. The end wall is 9 in. thick. The temperature of the furnace interior is 2600 F. How much heat is lost through the opening?

The ratio of width of opening to thickness of wall is

$$D/X = 9 \text{ in.}/9 \text{ in.} = 1.00$$

Considering the opening as rectangular, the ratio of the sides is 84 in./9 in., or 9.33. Reading from the uppermost curve of Fig. 2, for very long slots and for $D/X = 1.00$, the radiation factor is found to be 0.68. This is increased about 7 per cent by convection heat transfer. The amount of heat radiated is

$$Q = 0.68 \times 0.172 \times \frac{84 \times 9}{144} \times \left[(30.60)^4 - (5.60)^4 \right] \times 1.07$$

$$= 575{,}700 \text{ Btu per hr.}$$

Example 2. In a double-chamber furnace, the combustion chamber is maintained at 2500 F, and it is required to transmit 500,000 Btu per hr to the heating chamber at 2000 F, and to distribute the heat uniformly therein. For this purpose, perforations or heat ports are to be provided in a curtain wall between the chambers. The area of the wall is 48 sq ft, its thickness is 9 in., and the material is firebrick. The ports are to be $2^1/_2$ in. high by $4^1/_2$ in. wide. How many such ports are required?

Let the number of ports be n. The ratio of the sides of the rectangular openings is $4^1/_2/2^1/_2$, or 1.80. The ratio of least width of opening to wall thickness is $2^1/_2/9$, or 0.278. By interpolating in Fig. 2 between the curve for the 2-to-1 rectangle and the square, the total-radiation factor is found to be 0.29. For such long, narrow openings the increase by convective heat transfer is negligible (unless there is actual flow of hot gases through the ports from one chamber to the other). The equation then becomes

$$500{,}000 = n \times \frac{2\frac{1}{2} \times 4\frac{1}{2}}{144} \times 0.172 \times 0.29 \times \left[(29.6)^4 - (24.6)^4 \right] \text{heat radiated} + \left[48 \text{ sq ft} - \frac{n \times 2\frac{1}{2} \times 4\frac{1}{2}}{144} \right] \times \frac{10 \text{ Btu/sq ft, hr., °F/in.}(2500 - 2000)}{9 \text{ in.}} \text{ heat conducted}$$

from which $n = 312$. This means that 312 heat ports are re-

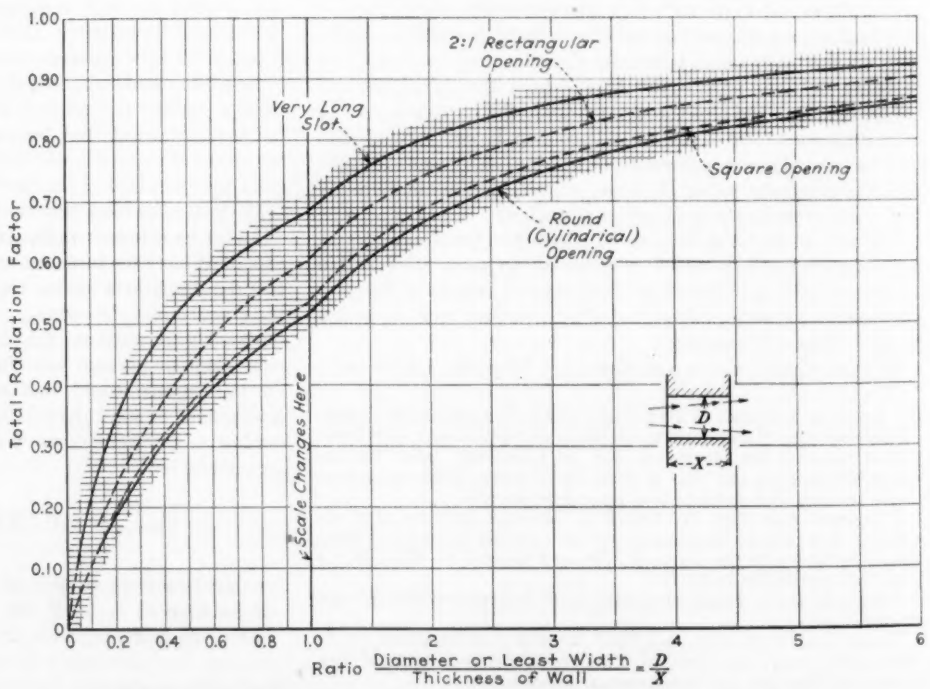

FIG. 2 FACTORS FOR TOTAL RADIATION THROUGH OPENINGS OF VARIOUS SHAPES

quired, having a combined area equal to about 50 per cent of the total area of the curtain wall.

When doors are open only part of the time, a modification of the radiation factor is required, as shown elsewhere.

2 Derivation of Fundamental Equations

The fundamental principles involved in the calculation of radiant-heat interchange between finitely bounded surfaces, and the application of those principles to some of the problems involving direct radiation between various surface arrangements, have been presented by several investigators (2–7). For the present purpose it is sufficient to say that the result, in every case of direct radiant interchange between two perfect radiators, is presentable in the form:

$$q = (\mathbf{E}_1 - \mathbf{E}_2) \cdot A \cdot F \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

in which q is the net direct heat interchange between the two surfaces, $\mathbf{E}_1$ and $\mathbf{E}_2$ their respective emissive powers,[4] A is the area of one of the two surfaces, and F is a factor which has variously been called the interchange factor or angle factor or area factor, and is equal to that fraction of the radiation, leaving A in all directions, which is intercepted within the bounds of the other surface. The factor F is plainly a geometrical one, dependent not on the shape of the radiating and receiving surfaces, but on the solid angle filled by the rays. Whether the radiators are plane surfaces, curved surfaces, or apertures is immaterial to the mathematical problem involved; but for convenience in the derivations both the interior of the furnace and the exterior surroundings (in the case of radiation through an opening in the furnace wall) or the muffle wall or electric resistor and the tube bank or cold stock (in the case of radiation within an oil still or an electric heating furnace) are considered to be replaced by equivalent flat diaphragms, indicated by 1–2–3 and 4–5–6 in Fig. 1. The problem then resolves itself into finding the radiant-heat interchange between two plane parallel black bodies or perfect radiators, maintained at uniform but different temperatures and separated by non-conducting but reradiating walls. The connecting walls will vary in temperature, consequently in emissive power, from one end to the other of the system. The direct radiation is readily calculable, but the reradiation cannot be evaluated without first determining how the emissive power varies along the walls.

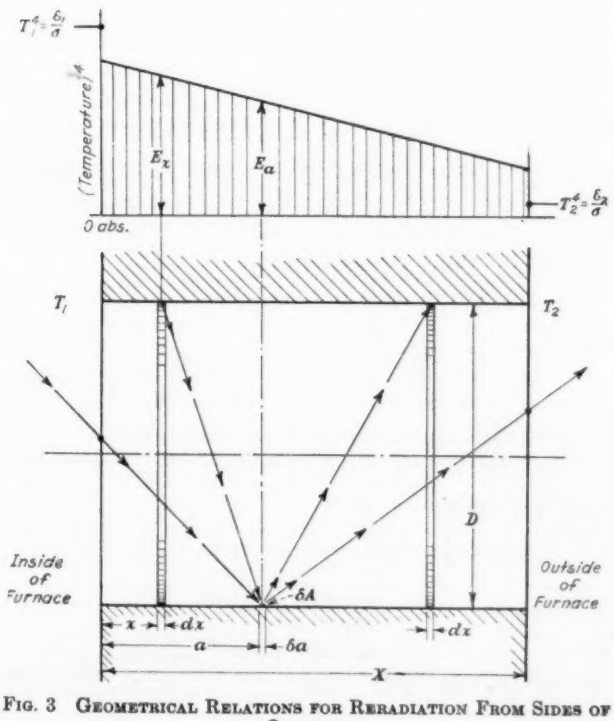

Fig. 3 Geometrical Relations for Reradiation From Sides of Opening

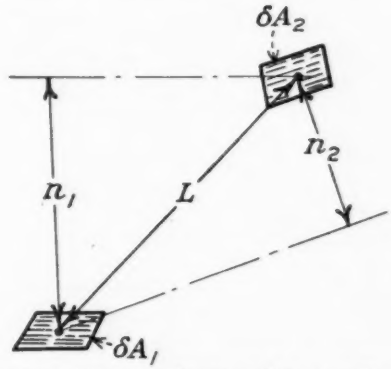

Fig. 4 Radiation Between Surfaces Small in Comparison to Their Distance Apart

The fundamental principles involved are two: namely, that the intensity of radiation is the same in all directions and that the radiation from a given area in a direction at an angle to the normal to the surface is proportional to the cosine of the angle (Lambert's principle). From these it can be shown that for any two infinitesimal black-body elements δA_1, δA_2, at any distance and relative position (Fig. 4) and having emissive powers $\mathbf{E}_1$, $\mathbf{E}_2$, the net heat interchange is

$$\delta q = (\mathbf{E}_1 - \mathbf{E}_2) \cdot \delta A_1 \cdot \delta A_2 \cdot \frac{n_1 \cdot n_2}{L^4} \quad \ldots\ldots\ldots [3]$$

where L is the actual distance between δA_1 and δA_2, n_1 the perpendicular distance from δA_1 to a plane through the center of δA_2 parallel to δA_1, and n_2 the perpendicular distance from δA_2 to a plane through the center of δA_1 parallel to δA_2.

3 Calculation of Direct Radiation

Finding the factor F for direct radiation between any two equal finite surfaces, each at constant temperature over its whole area, such as the equivalent diaphragms 1-2-3 and 4-5-6, requires quadruple integration over the areas. Evaluations of the factor for all of the four shapes considered here have been reported in the literature (2, 5, 7) and are presented in the second column of Table 1. Here, as in all of the following discussion, the smallest dimension D of the areas is taken as unity, and x represents the distance between the radiating areas as a *ratio* to their smallest dimension. The variation of the factor F with the distance ratio x is shown graphically in Fig. 5, for the various shapes.

4 Reradiation From the Side Walls

Let S_1 and S_2 represent opposed plane areas or radiators of equal area S, separated by a distance X, and at absolute temperatures T_1 and T_2, respectively. Part of the heat radiated from area S_1 strikes the side walls, is absorbed by them, and is reradiated from these walls to area S_2. Assuming for the present that the side walls (or sides of the opening) are non-conducting (or at least that the heat conducted by them is negligible compared to the heat radiated), it is evident that the total heat radi-

[4] The emissive power of a surface is its rate of emission of radiant energy per unit of area. For a black or perfect radiator it is equal to σT^4, in which T is its absolute temperature and σ is a constant, the Stefan-Boltzmann constant.

ated *to* any small area δA on the side walls must be exactly equal to the heat radiated *from* δA. Points on the sides near surface S_1 receive heat from it more readily than they radiate heat to surface S_2, while for points on the sides near S_2 the reverse is true.

Referring now to Fig. 3, a heat balance for an element δA, of

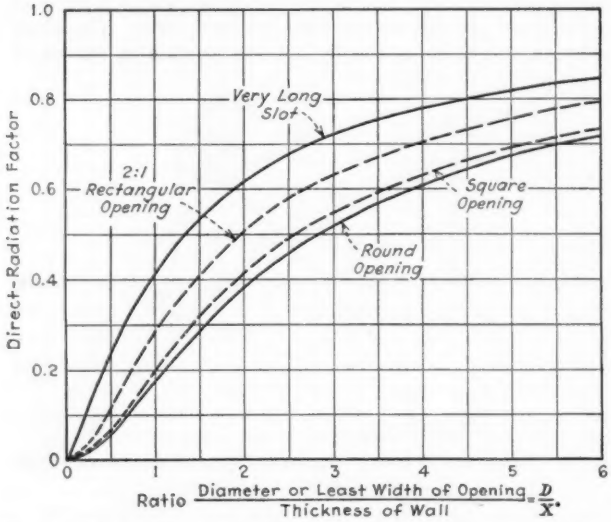

FIG. 5 DIRECT-RADIATION FACTORS FOR OPENINGS OF VARIOUS SHAPES

width δA, located at a distance a from one end of the system, yields the following equation:

$$\underset{\substack{\text{Radiation from}\\ \delta A \text{ in all}\\ \text{directions}}}{E_a \cdot \delta A} = \underset{\substack{\text{Radiation to}\\ \delta A \text{ from end}\\ \text{at } x = 0}}{\mathbf{E}_1 \cdot \phi(a) \cdot \delta A} + \underset{\substack{\text{Radiation to } \delta A\\ \text{from sides between}\\ x = 0 \text{ and } x = a}}{\int_0^a E_x \cdot f(a - x) \cdot \delta A \, . \, dx} + \underset{\substack{\text{Radiation to } \delta A\\ \text{from sides between}\\ x = a \text{ and } x = X}}{\int_a^x E_x \cdot f(x - a) \cdot \delta A \cdot dx} + \underset{\substack{\text{Radiation to } \delta A\\ \text{from end at } x = X}}{\mathbf{E}_2 \cdot \phi(X - a) \cdot \delta A}$$

where

$\mathbf{E}_1$ and $\mathbf{E}_2$ are the fixed emissive powers of the end surfaces or apertures S_1 and S_2

E_a (or E_x) is the variable emissive power of the connecting wall, at $x = a$ (or x)

$\phi(x)$ is a fraction, of direct radiation from an element of area δA of width δx, running around the walls connecting the planes S_1 and S_2, which is intercepted by an area S at distance x from δA

$f(x) \cdot \delta x'$ is a fraction, of radiation from an element of area $\delta A (= P \cdot \delta x)$ around the walls, which is intercepted by another element of area $\delta A' (= P \cdot \delta x')$ around the walls, and separated from the first by a normal distance x

P is the perimeter of radiator S_1 or S_2.

Dropping out the δA, the equation becomes:

$$E_a = \mathbf{E}_1 \cdot \phi(a) + \mathbf{E}_2 \cdot \phi(X - a) + \int_0^a E_x \cdot f(a - x) \cdot dx + \int_a^X E_x \cdot f(x - a) \cdot dx \quad \ldots\ldots [4]$$

The functions $\phi(x)$ and $f(x)$ are related to each other and to the function $F(x)$. If the fraction $F(x)$ of the radiation from S_1 is intercepted by S_2, the fraction $-\dfrac{dF(x)}{dx} \cdot \delta x$ will be intercepted by the side-wall strip of width δx, lying between the two plane areas S_2 located at distances x and $x - \delta x$, respectively, from the radiator S_1. By the principle of reciprocity this latter fraction, multiplied by the area S, must equal the area δA multiplied by the fraction $\phi(x)$ of its radiation which is intercepted by S. Therefore:

$$-S \cdot \frac{dF(x)}{dx} \cdot \delta x = \phi(x) \cdot \delta A$$

Since area δA equals $P \cdot \delta x$, it follows that

$$\phi(x) = -\frac{S}{P} \cdot \frac{dF(x)}{dx} = -\frac{S}{P} \cdot F'(x) \quad \ldots\ldots [5]$$

Similarly, if $\phi(x)$ represents the fraction of the radiation from δA which is intercepted by S at a distance x from δA, then $-\dfrac{d\phi(x) \cdot \delta x'}{dx}$ represents the fraction intercepted by the strip of area $\delta A' (= P \cdot \delta x')$, between two surfaces S located at distances x and $x - \delta x$, respectively, from radiator δA. This fraction, by definition, is equal to $f(x) \cdot \delta x'$. Then

$$f(x) \cdot \delta x' = -\frac{d\phi(x)}{dx} \cdot \delta x'$$

$$f(x) = \frac{-d\phi(x)}{dx} = -\phi'(x) = \frac{n \cdot D}{2(n+1)} \cdot F''(x) \quad \ldots\ldots [6]$$

where n is the ratio of the long to the short side of the area S.

While the factors $\phi(x)$ and $f(x)$ can be obtained by integration

TABLE 1 INTERCHANGE FACTORS

Infinite strips or slots...	$\sqrt{x^2+1} - x$	$\frac{1}{2} - \frac{x}{2\sqrt{x^2+1}}$	$\frac{1}{2(x^2+1)^{3/2}}$

of the fundamental Equation [3], they can also be arrived at, in a more simple manner, by successive differentiations of the expression for $F(x)$. The resulting expressions for $\phi(x)$ and $f(x)$ applying to the various shapes which are to be considered—circular disks, squares, 2-to-1 rectangles, and 1-to-∞ rectangles or infinite strips (slots, if the radiators are apertures instead of surfaces)—are presented in Table 1. The quantity x is the ratio of the distance between the surfaces to their smallest dimension D, which is assumed as unity.

If, as stated above, n is the ratio of long to short side of the area S, then S/P equals $nD/2(n + 1)$ for all four shapes if n is considered unity for circles.

If Equation [4] can be solved to give E_a as a function of a, the relationship thus determined can be used to find the desired total net interchange between the two ends of the system, which will be:

$$q = (\mathbf{E}_1 - \mathbf{E}_2) \cdot F(X) \cdot S + \int_0^X (\mathbf{E}_1 - E_a) \cdot \phi(a) P dA \quad \ldots [7]$$

Equation [4] may be simplified somewhat, without loss of generality, by taking the fixed emissive powers $\mathbf{E}_1$ and $\mathbf{E}_2$ of the two ends as 1 and 0, respectively. The final result will then be the net heat transmission between the two ends, per unit difference of their emissive powers, and can readily be converted to any other form desired. Equation [4] becomes:

$$E_a = \phi(a) + \int_0^a E_x \cdot f(a - x) \cdot dx + \int_a^X E_x \cdot f(x - a) \cdot dx \ldots [8]$$

This is an integral equation[5] of the second, or non-homogeneous, or Poisson-Volterra-Fredholm type, and is to be solved for E_a, after which the net heat interchange may be evaluated from Equation [7].

5 Solution of Equations

Of the methods available for solving Equation [8], one which dodges some complications inherent in an exact solution and which can be extended to any desired degree of precision follows from the assumption that E_a does not vary continuously from $a = 0$ to $a = X$. Instead, the walls from 0 to X are pictured as divided into m zones of equal width, each running completely around the wall and having a temperature (and consequently an emissive power) which is uniform over the zone, and in equilibrium with the rest of the system.

By such a procedure one obtains m equations linear in m unknown values of E, E_1 ..... E_m. Obviously, this procedure yields a solution which approaches the exact truth as m approaches infinity. The number of equations and unknown E's can be halved by including the condition that the emissive power is skew-symmetrical with respect to the center of the system $X/2$, at which point it has a value equal to the arithmetic mean of the emissive powers of the ends.

To try this method of solution the special case was considered of disks with diameters equal to twice the distance separating them. The walls were divided into six zones (three equations). The emissive power was found to vary linearly with the position of the midpoint of each segment, to three significant figures (see Table 2, left half). However, when the condition of linear variation of E was set into the integral Equation [8] in an attempt to solve it, the result indicated that E_x cannot be truly linear with x. To straighten out this point, the walls were divided into eight zones and the calculations carried out sufficiently far to guarantee five significant figures in the final E's obtained. The results, presented in Table 2, show a slight but definite departure of the $E - x$ relationship from a linear one. A comparison of the total change in emissive power along the wall from $x = 0$ to $x = X$ for the two cases, six zones and eight zones, shows agreement to three figures, indicating that six is an adequate number of zones into which to divide the walls.

TABLE 2 RESULTS OF SOLUTION BY DIVISION OF SIDE WALLS INTO ZONES

6 zones		Diff.	8 zones		Diff.
E_1...	0.645	0.058	E_1...	0.65239	0.04302
E_2...	0.587	0.058	E_2...	0.60937	0.04354
E_3...	0.529	0.058	E_3...	0.56583	0.04379
E_4...	0.471	0.058	E_4...	0.52204	0.04408
E_5...	0.413	0.058	E_5...	0.47796	0.04379
E_6...	0.355		E_6...	0.43417	0.04354
			E_7...	0.39063	0.04302
$E_0 - E_X$, by extrapolation, = 0.348			E_8...	0.34761	
			$E_0 - E_X$, by extrapolation, = 0.3473		

With the variation in emissive power known, it is possible to determine the total interchange factor, i.e., the factor by which the free radiation from an unobstructed disk must be multiplied to give the direct radiation plus wall reradiation when the two disks are connected by non-conducting but reradiating walls. This factor is found to be 0.681, 0.677, 0.6725, or 0.6723, depending on whether the connecting walls are divided into one, two, six, or eight zones. From the result it is obvious that a division into six zones is entirely adequate for accuracy to three significant figures when $X = 1/2$.

The above-described method of calculating total interchange factors, although time-consuming, is interesting in its proof of how slightly the $E - x$ relationship varies from a linear one. This fact may be utilized to obtain a relatively simple solution of the general problem which, although inexact from a strict mathematical viewpoint, proves to be highly accurate. Let the total change in E along the connecting walls from $x = 0$ to $x = X$ be represented by Δ. The condition that E varies linearly with x and has a value of $1/2$ at $X/2$ is then:

$$E_x = \frac{1 + \Delta}{2} - \frac{\Delta}{X} \cdot x \ldots [9]$$

If this substitution for E_x is made in Equation [8], the latter becomes, after partial integration:

$$\frac{1 + \Delta}{2} \left\{ \phi(a) + \phi(X - a) \right\} - \frac{\Delta}{X} a - \phi(a) = -\frac{\Delta}{X} \int_0^a x \cdot f(a - x) \cdot dx - \frac{\Delta}{X} \int_a^X x \cdot f(x - a) \, dx \ldots [10]$$

The interrelationship of the functions f, ϕ, and F as given in Equations [5] and [6] permits an evaluation of the integrals appearing in Equation [10] and a solution of the latter for Δ. It is

$$\Delta = \frac{\phi(a) - \phi(X - a)}{\phi(a) - \phi(X - a) + \frac{n}{(n+1)X} [F(a) - F(x - a)]} \ldots [11]$$

If the assumption involved in obtaining Equation [11] were correct, i.e., that E_a varies linearly with a, one would expect

[5] "Integral equations" are not at all the same as ordinary equations containing integrals, differing from them in that the unknown function which is to be determined appears both in the integral and outside it. Integral equations are characteristic of problems involving *action at a distance*, in contradistinction to differential equations which apply only when *non-mediate action* occurs between adjacent points or objects in contact. The first-named equations are therefore especially likely to appear in radiation problems, since radiation is action at a distance. Nevertheless, from the purely mathematical standpoint, integral equations and differential equations often lead to an identical result, and certain problems can be solved equally well by the use of either type of equations. An attempt to reconcile the opposing philosophical concepts of action at a distance and direct or non-mediate action, in the case of radiation, has been made by G. N. Lewis in "The Anatomy of Science," using the relativity theory.

Equation [11] to yield a value of Δ dependent on X alone, with a not involved. It does not, as expected, because E_a is very closely, but not exactly, linearly proportional to a. However, that value of Δ may be determined from Equation [11] which satisfies any particular value of a, such as $a = 0$. Physically, the meaning of the result so obtained would be this: An emissive power gradient would have been determined which would permit the wall strip adjacent to one end to exist in perfect thermal equilibrium, i.e., it would be receiving exactly as much heat from the end at $x = 0$ as it was reradiating to the strips beyond it and to the other end. But no other strip, except at $X/2$ and X, would be quite in equilibrium. If a is set equal to zero, Equation [11] becomes:

$$\Delta = \frac{1 - 2\phi(X)}{1 - 2\phi(X) + \dfrac{2n}{(n+1)X} \cdot (1 - F(X))} \quad \ldots\ldots [12]$$

The same result would be obtained by letting $a = X$. Equation [9], with a value for Δ obtained from Equation [12], although not mathematically exact, shows the variation of emissive power along the walls with an error affecting only the fourth or fifth significant figure.

Of more interest than the emissive power gradient along the walls, however, is the net interchange of radiation between the ends of the system, which will not be sensitive to any slight error in emissive power gradient. Equation [7] gives the heat interchange. If $\mathbf{E}_1$ and $\mathbf{E}_2$ are 1 and 0, respectively, [7] becomes:

$$q = F(X) \cdot S + \int_0^X (1 - E_a) \cdot \phi(a) \cdot P \cdot da \ldots\ldots [7']$$

The above may be compared to the interchange between a radiator of unit emissive power, free to radiate in all directions, and its surroundings of zero emissive power. For a radiator of area S, the free radiation would be $1 \times S$. The ratio q/S may therefore be considered the total interchange factor, and will be called $\mathbf{F}$. From Equation [7'],

$$\mathbf{F} = F(X) + \frac{P}{S} \int_0^X (1 - E_a) \cdot \phi(a) \cdot da \ldots\ldots [13]$$

The total interchange factor $\mathbf{F}$ is seen to consist of the sum of two quantities, the direct radiation factor F and the second term, which may be spoken of as the reradiation factor.

Returning to the approximation method and substituting $(1 + \Delta)/2 - \Delta a/X$ for E_a, and $2(n+1)/n$ for P/S, and partially integrating, one obtains finally:

$$\mathbf{F} = F(X) + \left(\frac{\Delta a}{X} + \frac{1 - \Delta}{2}\right) \cdot (1 - F(X)) + \frac{\Delta}{X} \int_0^X F(a) \cdot da \quad [14]$$

Equations [12] and [14] constitute the desired solution of the general problem, and may now be applied to the solution of the special cases of interest.

Disks. Equation [12], on substitution of $\phi(X)$ and $F(X)$ from Table 1, yields:

$$\Delta = \frac{\sqrt{X^2+1} + 2X\sqrt{X^2+1} - 2X^2 - 1}{\sqrt{X^2+1} + 1} \quad \ldots\ldots [15]$$

Equation [14], on substitution of Δ from [15], $F(X)$ from Table 1, and integration, yields:

$$\mathbf{F} = F(X) + \frac{1 - \Delta}{2}(1 - F(X)) + \frac{4\Delta}{3X}\left(\sqrt{X^2+1}\left(X^2 - \frac{1}{2}\right) - X^3 + \frac{1}{2}\right) \ldots\ldots [16]$$

Strips (or Infinite Slot)

$$\Delta = \frac{X^2}{2(1+X)\sqrt{X^2+1} - X^2 - 2} \quad \ldots\ldots [17]$$

$$\mathbf{F} = F(X) + \frac{1 - \Delta}{2}(1 - F(X)) + \frac{\Delta X}{2} - \frac{\Delta\sqrt{X^2+1}}{2} + \frac{\Delta}{2X} \log_e \left(X + \sqrt{X^2+1}\right) \ldots\ldots [18]$$

The results of the calculations based on Equations [15] to [18] have already been discussed and presented graphically in Fig. 2.

6 More Generally Applicable Method of Solving Integral Equation [4]

Although Equations [12] and [14] constitute a solution which is wholly adequate from an engineering viewpoint, the method used is in a sense a dodge, and would not have been applicable but for the almost perfectly linear variation of emissive power along the walls. A straightforward solution of general applicability is desirable as an indication both of the precision of the above method and of how other engineering problems leading to integral equations may be attacked.

This method, as originally developed by E. T. Whittaker (8), and as used by H. Buckley(9) to find the radiation from the interior of a hollow cylinder at constant temperature, is a logical development from the considerations that the integral of an exponential (e^{kx}) is equal to a constant times the exponential itself, and that the "nucleus" of the equation—that is, the $f(-)$ function—can be approximated to any desired degree of accuracy by a series of exponentials if a sufficient number of terms be used. The method consists of first finding expressions for $f(b)$ and $\phi(a)$ in the form of a series of exponential terms, of known coefficients and exponents; writing E_a also in the form of a series of exponentials, but with unknown exponents and coefficients; substituting these in Equation [4] or [8], integrating, and solving for the unknown constants. The form of E_a is thereby determined. As stated, any desired degree of accuracy can be attained by using a sufficient number of exponential terms. For the present purpose, two terms each for $f(b)$ and $\phi(a)$, i.e.:

$$f(b) = P \cdot e^{pb} + Q \cdot e^{qb} \ldots\ldots [19]$$

($b = (x - a)$ or $(a - x)$, always positive)

$$\phi(a) = R \cdot e^{ra} + S.e^{sa} \ldots\ldots [20]$$

were found to be quite sufficiently accurate for values of D/X less than 5.

The closeness with which the actual values of $f(b)$ and $\phi(a)$ can be approximated by two-term exponential expressions is evident from Table 3, which applies to round openings when $X/D = a = 1$. The exponential expressions for this particular shape and proportion are:

$$f(b) = 1.282e^{-2.405b} - 0.282e^{-6.355b} \ldots\ldots [19a]$$

$$\phi(a) = 0.5305e^{-2.286a} - 0.0305e^{-6.86a} \ldots\ldots [20a]$$

TABLE 3

1.0.....	0.116	0.1152	0.0607	0.0543

By Whittaker's method, it was found that when the two-term exponential expressions, Equations [19] and [20], are used for $f(b)$ and $\phi(a)$, the solution of integral Equation [4] has the form:

$$E_a/\sigma = A \cdot e^{\alpha a} + B \cdot e^{\alpha(X-a)} + C \cdot e^{\beta a} + D \cdot e^{\beta(X-a)} + E \cdot e^{\gamma a} + F \cdot e^{\gamma(X-a)} + G \cdot e^{\delta a} + H \cdot e^{\delta(X-a)} \quad [21]$$

the coefficients A to H and the exponents α and β being unknown. E_x is the same except that x is substituted for a in all terms.

Substituting these expressions for E_a and E_x in the integral Equation [4] and integrating, furnishes:

$$\left(1 - \frac{P}{\alpha - p} - \frac{Q}{\alpha - q} + \frac{P}{\alpha + p} + \frac{Q}{\alpha + q}\right) \cdot (Ae^{\alpha a} + Be^{\alpha(X-a)}) + \left(1 - \frac{P}{\beta - p} - \frac{Q}{\beta - q} + \frac{P}{\beta + p} + \frac{Q}{\beta + q}\right) \cdot (Ce^{\beta a} + De^{\beta(X-a)}) = \left(\mathbf{E}_1 R/\sigma - E + \frac{EP}{r - p} + \frac{EQ}{r - q} - \frac{EP}{r + p} - \frac{EQ}{r + q}\right) \cdot e^{\gamma a} + \left(\mathbf{E}_2 R/\sigma - F + \frac{FP}{-r - p} + \frac{FQ}{-r - q} - \frac{FP}{-r + p} - \frac{FQ}{-r + q}\right) \cdot e^{\gamma(X-a)} + \left(\mathbf{E}_1 S/\sigma - G + \frac{GP}{s - p} + \frac{GQ}{s - q} - \frac{GP}{s + p} - \frac{GQ}{s + q}\right) \cdot e^{\delta a} + \left(\mathbf{E}_2 S/\sigma - H - \frac{HP}{s + p} - \frac{HQ}{s + q} + \frac{HP}{s - p} + \frac{HQ}{s - q}\right) \cdot e^{\delta(X-a)} + \left(\frac{-AP}{\alpha - p} + \frac{Bp \cdot e^{\alpha X}}{\alpha + p} - \frac{CP}{\beta - p} + \frac{DP \cdot e^{\beta X}}{\beta + p} - \frac{EP}{r - p} + \frac{FP \cdot e^{\gamma X}}{r + p} - \frac{GP}{s - p} + \frac{HP \cdot e^{\delta X}}{s + p}\right) \cdot e^{\beta a} + \left(\frac{AP \cdot e^{\alpha X}}{\alpha + p} - \frac{BP}{\alpha - p} + \frac{CP \cdot e^{\beta X}}{\beta + p} - \frac{DP}{\beta - p} + \frac{EP \cdot e^{\gamma X}}{r + p} - \frac{FP}{r - p} + \frac{GP \cdot e^{\delta X}}{s + p} - \frac{HP}{s - p}\right) \cdot e^{\beta(X-a)} + \left(\frac{-AQ}{\alpha - a} + \frac{BQ \cdot e^{\alpha X}}{\alpha + q} - \frac{CQ}{\beta - q} + \frac{DQ \cdot e^{\beta X}}{\beta + q} - \frac{EQ}{r - q} + \frac{FQ \cdot e^{\gamma X}}{r + q} - \frac{GQ}{s - q} + \frac{HQ \cdot e^{\delta X}}{s + q}\right) \cdot e^{qa} + \left(\frac{AQ \cdot e^{\alpha X}}{\alpha + q} - \frac{BQ}{\alpha - q} + \frac{CQ \cdot e^{\beta X}}{\beta + q} - \frac{DQ}{\beta - q} + \frac{EQ \cdot e^{\gamma X}}{r + q} - \frac{FQ}{r - q} + \frac{GQ \cdot e^{\delta X}}{s + q} - \frac{HQ}{s - q}\right) \cdot e^{q(X-a)} \quad [22]$$

The values of α and β are determined by equating the coefficients of $e^{\alpha a}$ and $e^{\beta a}$ to zero:

$$1 - \frac{P}{\alpha - p} - \frac{Q}{\alpha - q} + \frac{P}{\alpha + p} + \frac{Q}{\alpha + q} = 0$$

$$1 - \frac{P}{\beta - p} - \frac{Q}{\beta - q} + \frac{P}{\beta + p} + \frac{Q}{\beta + q} = 0$$

Adding and clearing of fractions:

$$(\alpha^2 - p^2) \cdot (\alpha^2 - q^2) - 2P \cdot p \cdot (\alpha^2 - q^2) - 2Q \cdot q \cdot (\alpha^2 - p^2) = 0$$

This expression is solved for each case by substituting the proper values of P, Q, p, and q, and solving the quadratic. For the round opening of $X = D$, $P = 1.282$, $Q = -0.282$, $p = -2.405$, $q = -6.345$, and the resulting values are $\alpha = -0.3563$ and $\beta = -6.58$.

Next, the coefficients of $e^{\gamma a}$ and $e^{\gamma(X-a)}$ in Equation [22] are equated to zero to find E and F; coefficients of $e^{\delta a}$ and $e^{\delta(X-a)}$ are equated to zero to find G and H. Finally, the coefficients of $e^{\beta a}$, $e^{\beta(X-a)}$, e^{qa}, and $e^{q(X-a)}$ in Equation [22] are equated to zero, using the values of α, β, E, F, G, and H as found above; this results in four simultaneous equations, which are then solved for the last four unknowns A, B, C, and D. It was found that each two successive coefficients, such as A and B or G and H, are identical except that $\mathbf{E}_1$ and $\mathbf{E}_2$ are interchanged.

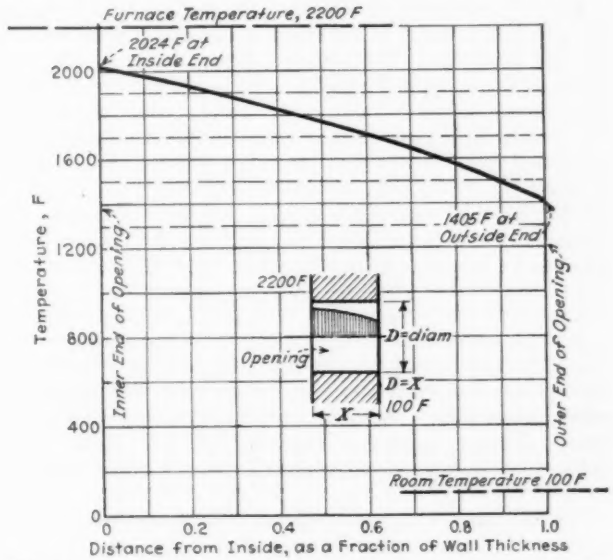

FIG. 6 TEMPERATURE VARIATION ALONG THE SIDE OF ROUND OPENING FROM INNER TO OUTER END

(For diameter = thickness of wall; 2200 F furnace temperature, 100 F outside temperature.)

For the round opening of $X = D$, the final solution is:

$$E_a = (1.261\mathbf{E}_1 - 0.6500\mathbf{E}_2) \cdot e^{-0.3563a} + (1.261\mathbf{E}_2 - 0.6500\mathbf{E}_1) \cdot e^{-0.3563(X-a)} + (0.0587\mathbf{E}_1 - 0.0053\mathbf{E}_2) \cdot e^{-6.58a} + (0.0587\mathbf{E}_2 - 0.0053\mathbf{E}_1) \cdot e^{-6.58(X-a)} - 0.05623\mathbf{E}_1 \cdot e^{-2.28a} - 0.05623\mathbf{E}_2 \cdot e^{-2.28(X-a)} - 0.0551\mathbf{E}_1 \cdot e^{-6.80a} - 0.0551\mathbf{E}_2 \cdot e^{-6.80(X-a)}$$

As previously stated, the equations can be simplified somewhat by taking $\mathbf{E}_1$ as unity and $\mathbf{E}_2$ as zero; then the above expression reduces to six terms.

On calculating and plotting numerical values for E_a, the graph was found to be an almost exactly straight line through $E_a = 1/2$ at $a = 1/2$. In agreement with the results obtained by the previously described method of dividing the sidewalls into a number of equal sections, however, the line was not absolutely straight, but had a very slight curvature. When the value of X (ratio of distance between end planes to diameter of ends) exceeded 5, the curvature became noticeable and was not quite symmetrical, indicating that for such high values of X, more than two exponential terms should be used for the $f(-)$ and $\phi(-)$ functions.

The straight-line relationships between E_a and a can be represented by Equation [9] given in the discussion of the first method of solution. If the actual emissive powers $\mathbf{E}_1$ and $\mathbf{E}_2$ of the two ends of the system are retained instead of using values of unity and zero to simplify the calculations, Equation [9] would be of the form:

$$E_a = \frac{\mathbf{E}_1 + \mathbf{E}_2}{2} + \Delta(\mathbf{E}_1 - \mathbf{E}_2) \cdot \left(\frac{1}{2} - \frac{a}{X}\right) \quad [23]$$

Δ being, as before, the fractional change in emissive power along the wall, i.e., now $(E_{a=0} - E_{a=X})/(\mathbf{E}_1 - \mathbf{E}_2)$. The approximate method of solution has already yielded Equation [11] for predicting Δ. The temperature of the wall at a is, of course, $\sqrt[4]{E_a/\sigma}$; and in Fig. 6 the emissive power has been converted to temperature for a special case, to show how the temperature along the walls may be expected to vary. Fig. 7 also shows the variation of T_a^4, for various shapes.

Given the variation of E_a with a, the method of determining the reradiation factor is the same as outlined in the preceding method of solution. When the reradiation factor is calculated by using the solution of Equation [22] for E_a and exact expressions for $\phi(a)$ given in Table 1, and then by using the two-term exponential expressions given in Equation [20], the agreement is close, and in agreement with the values obtained by using the first method of solution, Equations [12] and [14]. In Fig. 8 are plotted the reradiation factors for the various shapes. By adding to these factors the direct radiation factors (section 3 and Fig. 5), the total-radiation factors of Fig. 2 were obtained.

7 Modifying Factors

In the mathematical work it has been necessary to assume that the sides of the opening are non-conducting and have black-body absorptivity and emissivity (i.e., reflect none of the radiation which strikes them). Actually, neither of these two conditions is exactly fulfilled. Heat conduction through the material of the sides of the opening would tend to increase the reradiation by

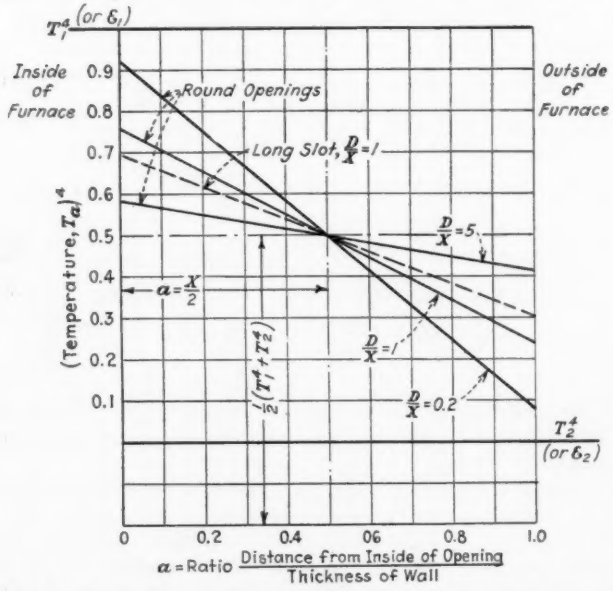

Fig. 7 Variation of Emissive Power or Fourth Power of Absolute Temperature of Sides of Opening, From Inner to Outer End

transferring heat from the inner to the outer part of the sides, whence it can be radiated more freely. In openings in walls of refractory material such as firebrick, conduction is so small compared to radiation that the error from this source is negligible in industrial furnaces.

The effect of partial reflection of heat rays from the sides is to increase the total amount of heat radiated through a given opening. As an extreme case, if the walls were perfectly reflecting (or absorbed none of the radiation), the total-radiation factor would be increased to unity for all openings,[6] and the opening would be equivalent to a freely exposed diaphragm. For rough surfaces such as firebrick, however, reflection plays only a minor part. Data on emissivity of brick surfaces are scarce and uncertain, but the value apparently lies between 80 per cent and 92 per cent of that of the black body. The proportion of heat reflected is therefore small, and since the reflection from such surfaces is almost all diffuse rather than specular, most of the rays strike the walls several times before escaping, and undergo 80

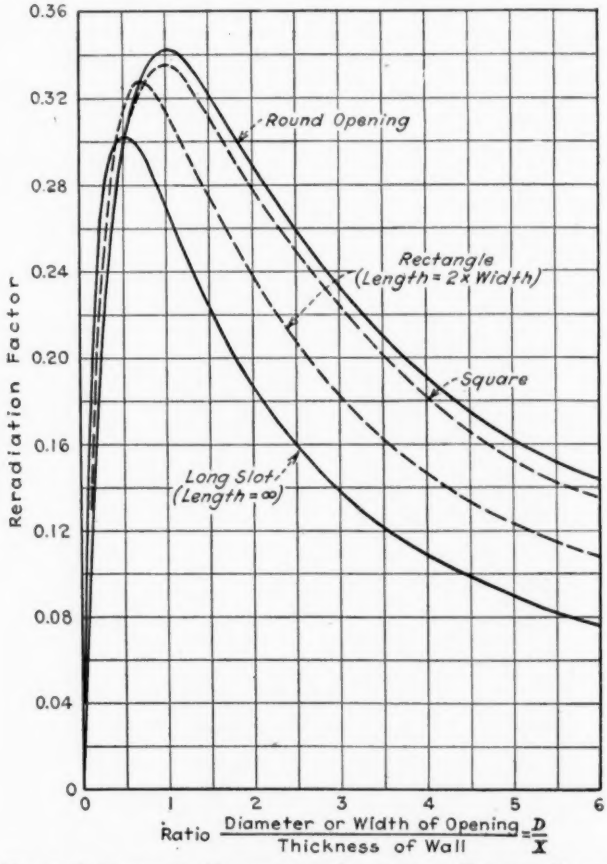

Fig. 8 Reradiation Factors for Openings of Uniform Cross-Section

to 92 per cent absorption each time. That the modification required in the reradiation factor due to reflection is negligible, is confirmed by the tests described in the following section, in which the heat absorbed by the calorimeter checked almost exactly with the sum of direct radiation plus reradiation as calculated from the measured temperature of the sides, neglecting reflection.

The factor which is actually of greatest importance in modifying the mathematically derived results is the transfer of heat to those parts of the sides near the outer end of the opening, by circulation of gases within the opening. While the effect of this action might be estimated mathematically, so many assumptions would have to be made that it seems best to depend on factors derived from tests as explained in the following section.

An assumption implicit in the basic Equation [3] is the validity of Lambert's cosine principle. Actually, the intensity of radiation from all surfaces in directions at large angles from the normal is different from that required by the cosine principle. The few data that are as yet available as to the deviation, however, indicate that the overall error introduced by assuming the correctness of the cosine principle is not great.

The effect of variation of temperature around the perimeter of a

[6] The additional condition must be imposed that the reflection be mirror-like, not diffuse.

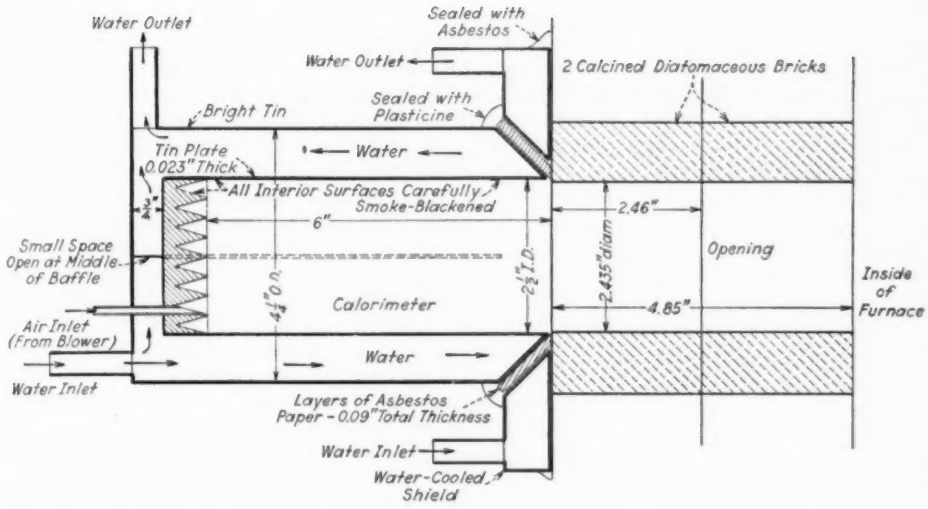

FIG. 9 CALORIMETER FOR MEASURING HEAT RADIATED THROUGH OPENING

square or rectangular opening has already been mentioned, but will be further discussed in section 8.

The factors of Fig. 2 will require modification if steady-state temperature conditions do not exist in the material of the sides of the opening. For instance, if a furnace door is opened only occasionally and remains closed during the greater part of the time, the sides of the door opening attain practically the temperature of the furnace interior at all points (except for the effect of conduction through the wall); whereas the outer door frame in which the door slides is not much above the temperature of the atmosphere. When the door is first opened, therefore, the rate of heat loss by radiation is the same as for a fully exposed diaphragm at the outside of the opening, and the total-radiation factor is unity. The sides of the opening at once begin to cool, however, and the factor decreases, becoming asymptotic to the values shown in Fig. 2 as the sides approach steady temperature conditions. How quickly the change occurs depends on the diffusivity of the material at the sides of the opening.

8 EXPERIMENTAL

In order to check the theoretical results and to determine the effect of the influences which had to be neglected in their development, tests were made of radiation through actual openings in furnace walls. The test arrangement is shown in Fig. 9. The heat radiated through the round openings was absorbed by the water calorimeter, the interior of which was carefully smoke-blackened. Temperature rise of the water was determined by calibrated thermometers. Quantity of water was determined by weighing over periods of 10 min, during which the temperatures remained practically constant. The temperature of the gas-fired furnace was determined by a platinum–platinum-rhodium thermocouple and by a calibrated optical pyrometer. A small amount of air was blown into the interior of the calorimeter through the tube shown, in order to keep it clear of burned gases that would absorb part of the radiation and would also cause condensation on the water-cooled surfaces.

The bricks, in the case of the round openings, were calcined diatomaceous bricks, held together by bolts. The hole was bored out in a lathe to a diameter of 2.435 in., care being taken to keep the edges of the opening sharp. The total thickness of the two bricks was 4.85 in., hence the ratio D/X was 0.502 (practically 1 to 2).

Temperatures at marked intervals along the side of the opening were determined by a contact thermocouple, consisting of chromel-alumel wires, butt-welded and the junction filed down to form a thin strip 0.09 in. wide (at the junction) by 0.018 in. thick (Fig. 10). During the time these measurements were being taken the calorimeter had to be removed, but the opening was closed by a metal plate having a slot for the thermocouple.

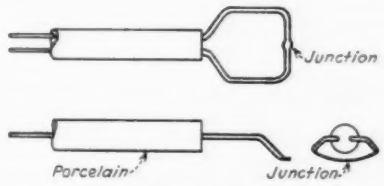

FIG. 10 CONTACT THERMOCOUPLE

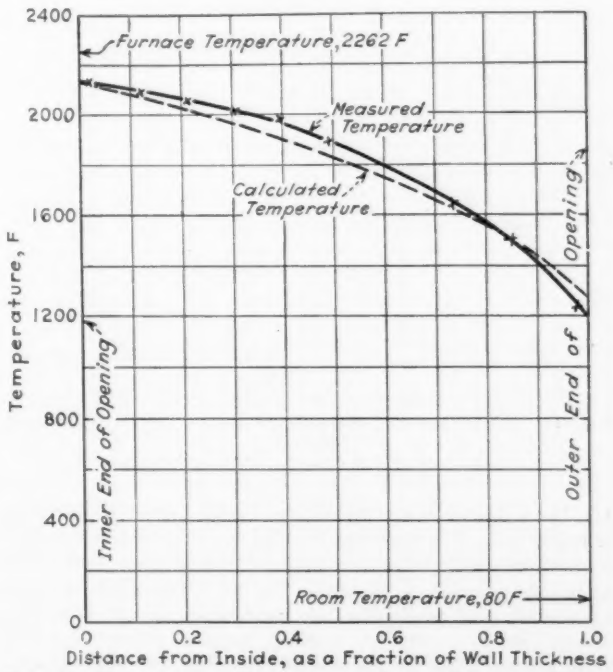

FIG. 11 TEMPERATURE DISTRIBUTION ALONG SIDES OF ROUND OPENING

(Diameter equal to 50.2 per cent of the wall thickness.)

The results of these tests on the round opening are shown in Table 4 and the temperatures in Fig. 11.

The remarkably close check between the quantity of heat as measured by the calorimeter and the amount calculated as direct radiation plus reradiation from the walls on the basis of the measured temperature distribution along the sides of the opening indicates that neither reflection nor variation from Lambert's law can be responsible to any large extent for the deviation from the theoretical figures.

The form of the temperature-distribution curves (solid line in Fig. 11) is very similar to the theoretical curve (broken line in Fig.

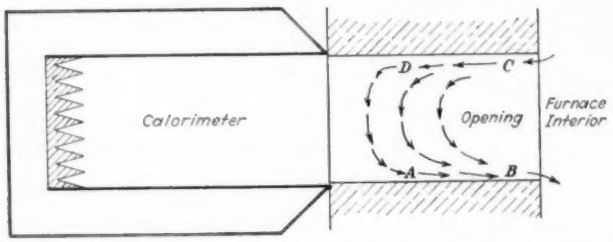

FIG. 12 CONVECTION OF HEAT BY CIRCULATION OF GASES WITHIN OPENING

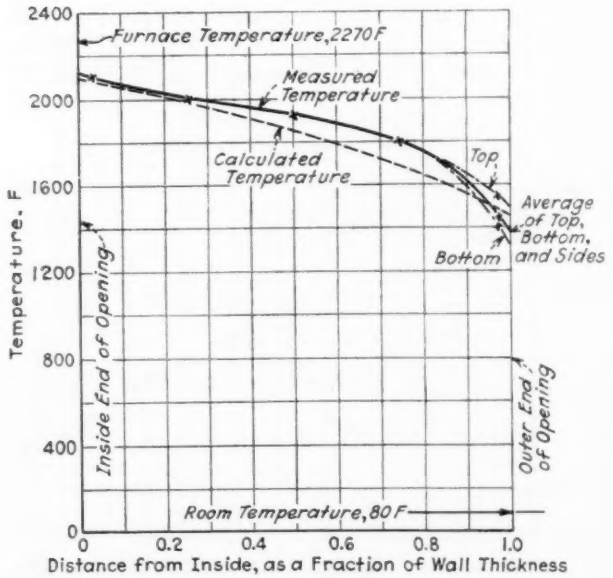

FIG. 13 TEMPERATURE DISTRIBUTION ALONG SIDES OF ROUND OPENING

(Diameter equal to 98.8 per cent of the wall thickness.)

11), but is higher in the middle and slightly lower at the outer or colder end. The explanation of this at once becomes evident from consideration of the circulation of gases which must occur within the opening, as shown in Fig. 12. The colder, heavier gases at A tend to displace the hotter gases at B; they flow toward the inside end of the opening, and are replaced by hotter gases floating along the top toward the outer end. The circulation carries heat from C to D and A. It may tend to cool points near B, but since this is the high-temperature end, radiation from the inside is so active that it prevents the temperature at C from dropping. The net result is a transfer of heat by convection toward the outer end of the opening and an increase of temperature at D and A. At the outer end, the top is higher than the bottom, as indicated by the dot-dash curves in Fig. 13.

As would be expected, the effect of convection is greater in an opening which is short in proportion to its diameter. This was shown by further tests in which the inner brick was removed, the single brick thickness of 2.46 in. then giving a ratio D/X equal to 0.988 (practically 1 to 1). The temperature distribution along the sides of the opening, as determined with the contact thermocouple, is shown in Fig. 13. The transfer of heat by convection to the outer end is even more clearly shown by the measurements in this case. In fact, with this comparatively wide opening in a thin wall, convection reached even into the calorimeter, as was evidenced not only by the difference of temperatures at the outer end of the opening, but especially by rapid condensation on the inner surfaces of the calorimeter, in spite of the blast of air blown through the tube. With the thought that the air inlet should have been at the top instead of at the bottom, the calorimeter was inverted; condensation still occurred as before, however, and the heat absorption was practically the same.

On account of this direct heat transfer from the furnace interior to the calorimeter by convection of gases, the heat absorption by the calorimeter was excessive, and the results were useless for determining radiation in this particular case. Since the tests with the first opening had shown, however, that the radiation calculated as the sum of direct radiation plus reradiation from the sides having the measured temperature distribution agrees almost exactly with the heat absorption of the calorimeter so long as there is no convective heat transfer to the latter, a similar calculation was carried out for the second opening. It resulted in a total-radiation factor of 0.551, as compared with the value 0.515 read from Fig. 2. This indicated that convection or circulation of gases within the opening increased the total radiation of heat by 7 per cent in this second opening (D/X = approximately 1 to 1).

A rectangular opening was next tested, to determine whether the assumption made in sections 5 and 6 that the variation of temperature around the perimeter of the opening in planes parallel to the end planes could be neglected led to appreciable errors. This opening was 2.64 in. high by 4.50 in. wide in a firebrick wall 4.50 in. thick. Hence the ratio of sides was 1.71 and the ratio D/X was 0.587. Calorimeter measurements were not made, but temperatures were measured with the contact thermocouple in many different places on the top, bottom, and sides of the opening, the latter being closed at the outside by a metal plate which was kept cool. The results are shown in Fig. 14, many of the points of which represent several coinciding readings. At the inner edge, the temperatures never varied more than 10 F, but toward the outer end, where temperatures were lower and interradiation less active, the differences were quite large. These differences, again, were doubtless accentuated by convection or circulation of gases, which is well known to be more active near the middle of a rectangular passage than in the corners.

The measurements having been plotted in Fig. 14, the tedious task was next undertaken of calculating $\phi(a)$, the "angle factor" of radiation from the walls to the outer end of the opening, for each of the points at which measurements were taken. The products $(T_a^4 - T_2^4)\cdot\phi(a)$ were then plotted for top, bottom, and sides, and the average over the whole area of the walls of the opening was determined; from it, the reradiation to the outside was found. Adding to this the direct radiation (see Fig. 5) the total-radiation factor was found to be 0.493 for this opening. The corresponding value from Fig. 2 is 0.45; hence the actual radiation is $9^1/_2$ per cent more than the "theoretical" value.

As a further check, values of $(T_a^4 - T_2^4)$ corresponding to the temperatures of Fig. 14 were averaged (with regard to linear distance around perimeter) for each plane at a/X = 0.1, 0.2, etc. to 1.0, and each average was multiplied by the average value of $\phi(a)$ for the whole perimeter, intermediate between those values given by the expressions in Table 1 for n = 1 and 2. The total-radiation factor found by this method, which more nearly

corresponds to the assumptions for the rectangular opening in sections 5 and 6, is 0.476, or 5½ per cent higher than the "theoretical" figure. Roughly, then, it may be said that about half of the increase is due to the neglected variation of temperature

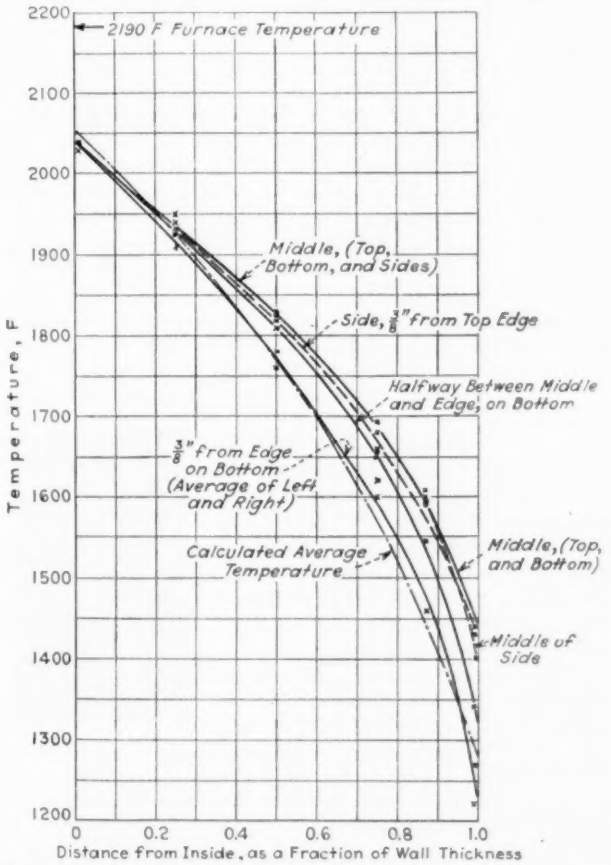

FIG. 14 TEMPERATURE DISTRIBUTION ALONG TOP, BOTTOM, AND SIDES OF RECTANGULAR OPENING

(Opening of 2.64 in. height, 4.50 in. thick, in wall 4.50 in. thick.)

around the perimeter, while the remaining half is caused by convection (and possibly, to a slight extent, by conduction through the fireclay). The latter figure checks well with the 4.2 per cent increase by convection in the first of the round openings, which had a ratio of width to wall thickness not very far different from that of the rectangular opening.

Where the axis of the opening is vertical instead of horizontal, as in the case of a furnace chamber with radiating surface under the roof and absorbing surface on the floor, or vice versa, it is probable that these convection factors would no longer apply; they would doubtless be decreased when the hotter surface is at the top and increased when it is at the bottom.

In the tests, any actual outward flow of gases was prevented by the calorimeter or by the cooled plate. In furnace openings where such flow does occur, the temperature of the sides will be raised still more. The additional heat loss cannot, however, be charged to radiation; in fact, radiation from the interior is actually reduced thereby, on account of the higher wall temperatures.

ACKNOWLEDGMENT

Mr. Keller wishes to acknowledge the assistance of Mr. Turner L. Smith in some of the mathematical derivations, of Mr. W. M. Geist in preparing the round openings, of Messrs. Nicholls and Reed of the Bureau of Mines in construction of the contact thermocouple, and of the authorities at Carnegie Institute of Technology for use of laboratory equipment.

Mr. Hottel wishes to acknowledge the assistance of Mr. D. M. Gordon in the numerical calculations of section 5.

Discussion

ROBERT B. SOSMAN.[7] One accidental "modifying factor" that needs to be looked out for in studying the radiation through an opening in a furnace where a water-cooled jacket is being used is the conversion of an absorbent surface into a reflecting surface by the condensation of water on the wall. We have observed this effect in experimenting with the radiation from an open-hearth furnace. In a tube containing no diaphragms, the condensation of a large number of small water drops on the inside of the water-cooled tube causes a surprisingly large increase in the radiation received, because the water drops act almost like specular reflectors, although the dry wall is of dull black metal and is a good absorber of radiation.

It might be worth while to call attention to the influence of wave length on reflection, especially at large angles of incidence. (This is discussed, for example, in R. W. Wood's "Physical Optics," New York, 1905, pp. 36–39.) Radiation that is incident nearly parallel to a surface is almost completely reflected if the wave length is comparable in size with the granules of the surface. This effect will be the more important the lower the temperature that is being measured, because the wave length of maximum intensity from a full radiator increases with falling temperature. Even the rough surface produced by cutting a hole in a fireclay brick will be a perfect reflecting surface for rays of the far infrared that strike the sides at angles of only a few degrees.

The Rolling and Extrusion of Aluminum and Its Alloys

By ROBERT L. STREETER,[1] PITTSBURGH, PA.

This paper outlines the history of the development of the manufacture of aluminum sheet, wire, and rod. It then discusses the growth of the demand for aluminum alloys and the problems that research laboratories and engineers had to solve before the manufacture of these alloys became practicable. A description is given of mills for rolling standard structural shapes, with reports on tests made to ascertain the power required to roll strong alloys. The extrusion of aluminum alloys is discussed, touching on the reasons for using extrusion in place of rolling, and explaining the limitations of the extrusion method of manufacturing shapes.

UNTIL 1914 the outstanding properties of aluminum were lightness and resistance to corrosion. It did not boast of strength and was not used where structural strength was required. Cooking utensils and automobile bodies were the principal outlets for sheet and electrical conductors for wire and rod. However, these conditions were changed, first, by the demands of the war in Europe and, second, by the possibilities opened up by the discovery by Wilm in 1912 that changed the whole future of the manufacture and application of aluminum. This discovery showed that certain aluminum alloys could be greatly improved by heat treating. The demands of the World War gave great impetus to research work based on Wilm's discovery, and the result was that group of high-strength aluminum alloys of which duralumin is typical. During the war and for ten years after, the output of duralumin was comparatively small and was absorbed almost entirely by the aircraft industry. But even though the quantities manufactured during that decade were small and the output took the form of small thin sheets demanded by the manufacturers of aircraft, considerable trouble was encountered in making the sheet. Research, however, came to the assistance of the mill man, and many of the difficulties were solved—not, however, without the expenditure of considerable sums for new equipment. The double-duo and continuous mills in use at that time were found to be quite inadequate for rolling duralumin sheet. For this purpose they were found to be deficient in power even though equipped with 800-hp or 1200-hp motors. Gears were too light, spindles and couplings too small, and housings too "springy" for rolling the new alloy.

About 1925 engineers in other lines than aircraft began to realize that if duralumin could be used to build a strong, light airship, it might be used to advantage to construct other strong and light machines. Great interest was shown by designers of trolley cars, railway cars, buses, trucks, traveling cranes, steamships, and many other structures moved by power. All of this interest resulted in a definite demand for large sheets and heavy plates, large rods for making rivets, large tubing of various sections, and structural shapes of a size never dreamed of when the first duralumin went into aircraft. As an example of the trend of these demands, designers of railway equipment insisted on channels and beams up to 14 in. and 85 ft long, heavy angles 6 by 6 in., 4-in. Z-bars, and rounds up to 8 in. in diameter, to say nothing of plates as thick as 1 in., with widths up to 132 in. and lengths to 90 ft.

Plans to meet these demands were under consideration by the Aluminum Company of America for several years before mills to take care of them were finally erected at Massena, N. Y., and Alcoa, Tenn., in 1928 and 1930. (See Figs. 1 and 2 for the blooming mill and the structural mill, respectively, at Massena.) It was no simple matter to build such mills and put them into operation. Experience had shown that what was good for steel was not necessarily good for aluminum. Much experimental and research work was demanded before design could be started. Rolling ingots weighing 3000 lb were needed. The heaviest used up to that time was about 250 lb. A heat-treating furnace 90 ft long was required, five times as long as the largest then in use. Soaking-pit temperatures must be held within extremely close limits. In order to secure best physical properties, quenching after heat treating must be done in a very few seconds. These are just a few of the problems that confronted the designers. How they were solved is shown in the description of the blooming and structural mills which follows.

The demands for the size of shapes to be rolled could be met by an ingot 20 by 20 by 72 in., and these were the dimensions used in the design. The melting and the casting of the ingots are accomplished along much the same lines used in steel open-hearth practice. Open-hearth furnaces with a capacity of 10 tons each are used, but without air preheating. Various fuels are used throughout the world for melting aluminum—coal, coke, oil, gas, wood, or electricity. In the plant under discussion the decision was to use coke.

The metal arrives at the furnaces in pigs that are similar to those used for iron in form and size, but they weigh only 50 lb. These pigs are melted down with the necessary alloying materials, which are usually rich alloys with aluminum. Magnesium, however, is added in the form of pure metal. Casting of the rolling ingots is done in heavy iron molds similar to those used for

[1] Consulting Engineer. Mem. A.S.M.E. Mr. Streeter received his M.E. degree from Pennsylvania State College, and then spent five years in the Engineering Department of the Lackawanna Steel Company at Buffalo, N. Y. After this came seven years at Rensselaer Polytechnic Institute as professor of steam- and gas-engine design. He went into the Ordnance Department of the Army in April, 1917, and was stationed at Rock Island Arsenal until discharged from service in October, 1919, with the rank of lieutenant-colonel. At this time he became chief mechanical engineer of the Aluminum Company of America at Pittsburgh and later was made vice-president of the United States Aluminum Company in charge of manufacture. He severed this connection in 1931 to take up private practice. Mr. Streeter was co-author with Dr. P. V. Faragher of a paper, "Aluminum and Its Light Alloys," presented at the Spring Meeting of the Society, Milwaukee, Wis., May 18 to 21, 1925. He served five years on the Main Research Committee of the Society and was an Associate Member of the Executive Committee of the Iron and Steel Division and represented the Society on the Division of Engineering of the National Research Council.

Contributed by the Iron and Steel Division for presentation at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. (Since the paper was delivered, the author has died.)

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

steel, and stripping is accomplished by means of a press instead of the standard stripping crane.

Electricity was available in large quantities and at reasonable cost; hence the decision to use electric soaking pits. As far as general arrangement is concerned, these pits follow steel-mill practice quite closely. Each pit accommodates five 20 by 20-in. ingots on end. The first installation consisted of 14 pits in one row, and the battery requires 2660 kw for heating. (See Fig. 3.) Temperature is maintained by automatic control, and recording pyrometers give continuous records of temperatures. All these instruments and the control desk are installed in a compact group in a central control room. One operator has complete control of the pits and issues the necessary instructions to the operating crew.

The control desk is worthy of special mention. It is made up of 14 sections, one for each pit, each section consisting of the following: (1) At the bottom of the front edge is a nameplate showing the number of the pit. (2) Just above the nameplate is the handle of the special Westinghouse type-W selector switch. (3) Immediately above the switch handle are three red lamps, one for each phase of the heating element in the pit. Each lamp is lighted only when current is actually flowing through the heating element in its respective phase, as determined by the automatic temperature control and the fact that none of the circuits has been accidentally opened. (4) The next five lamps are of different colors: clear, opal, blue, red, and green. These are dark or lighted according to the position of the selector switch. (5) At the top of the board is a graduated dial divided into 24 parts numbered for the 24 hours of the day. These dials are used in conjunction with pointers set at different time intervals to be determined after the proper cycle of operation has been learned by experience. The dial and pointers are to enable the operator to determine at a glance the proper operating program for each pit.

In addition to the signal lamps on the control desk, there are four lamps for each pit: red, green, amber, and opal. These are mounted on the roof of the control room where they can be readily seen by the mill-crane operator and the pit-cover-crane operator. These lamps constitute the mill signal board and burn in conjunction with the lamps of the same color on the control desk and serve to issue orders to the crane operators. It is apparent that there are more signal lamps on the control desk than on the mill board; the extra lamps on the desk are for condition signals only, while those common to both the control desk and the mill board are action signals and signify that some particular operation is required of the crane operator.

In order to increase the possible number of signals with the minimum number of lamps and to make some signals more noticeable than others, provision is made to energize the lamps from a steady or from a flashing source of current. All action signals are indicated by a flashing light. Steadily burning lamps indicate only an existing condition in the cycle of operations, requiring no action on the part of the crane operators. For instance, if the switch is on the first position, the green lamps burn steadily, indicating that the pit is empty but hot. When the switch is turned to position 2, the power is automatically cut off from the pit and the green light flashes, signifying that the pit is

to be charged. When the switch is on position 7, the power is on and the red lights are burning steadily, indicating that the pit is ready for discharge; but when the switch is put on position 8, the power is cut off and the red light flashes and the operators know that the pit should be unloaded.

The pit covers are handled by a special gantry-type crane which lifts them and carries them either forward or backward, giving a full pit opening for the operation of the pit crane. This latter crane is of the ordinary traveling type and utilizes automatic Gillert ingot tongs suspended from the crane hook.

(Each with a capacity of five 3000-lb ingots)

BLOOMING MILL

The selection of the size and type of blooming mill depended on many factors that are not usually met with in rolling steel. Among the many things taken into consideration were: (1) Size of ingot necessary to produce largest section, (2) shaped blooms for large sections, (3) rectangular blooms for small sections, (4) slabs for sheet and plate mills, (5) blooms for flat stock, and (6) numerous alloys to be rolled, these varying greatly in chemical composition and physical properties.

Different rolling speeds for the various alloys had to be taken into consideration. Owing to the nature of the aluminum business, in which buying is done in comparatively small quantities and warehousing on a country-wide plan had not yet been developed, roll changes would be frequent, necessitating a type of mill well adapted to frequent and rapid roll changes.

On account of the 20 by 20-in. ingot that had been decided on, it was thought best to use a 38-in. mill. One of the two-high reversing type was fixed upon. Rolling of flat slabs which necessitated edging passes fixed the roll face at 84 in. and the maximum lift of the top roll at 36 in.

Speed and power were not easily decided on, as there were no data available on the speed at which aluminum could be rolled on a blooming mill and on how much power would be required at the various speeds and for different alloys. In order to obtain data on which preliminary calculations could be based, permission was obtained from the Bourne-Fuller Company, Cleveland, Ohio, to roll a few ingots on their blooming mill. These ingots were cast at the Cleveland Works of the United States Aluminum Company, preheated there in an electric furnace, packed in silocel powder, and trucked to the Bourne-Fuller Works.

The rolling of these ingots indicated that power requirements would vary greatly with the alloys rolled. It was apparent from these tests that 17S alloy with physical properties comparable to duralumin required more power than open-hearth steel and that pure aluminum required about 37 per cent as much power as 17S. Taking the meager data obtained into consideration, the speed of the mill was fixed at a maximum of 120 rpm, and a motor with a nominal rating of 5000 hp was decided on.

The mill installed was built by the Mesta Machine Company and was in all general respects such a mill as would be used for rolling steel. On account of the softness of hot aluminum, it was necessary to hand-finish and polish all surfaces coming into contact with the metal rolled. This is found necessary generally to prevent all scratching and gouging of aluminum as it is being rolled, as such marks do not heal or roll out, but appear as defects in the finished piece.

This inherent characteristic of the metal prohibits carelessness of any kind in the rolling, and it also tends to discourage obtaining rolling costs comparable with those obtained in rolling steel.

The motors selected for the blooming-mill auxiliaries are rugged in construction and of ample power. Two screwdown motors are used, each of 150 hp. The manipulator and table motors are all of 85 hp each, and all these motors are controlled from the operating pulpit and are equipped with full magnetic control. The switchboard for all the motors is in the main motor room.

The bloom shear is worthy of special mention as it illustrates very clearly the proportions to which the aluminum-alloy business has grown and shows the trend of future development. This shear, which is placed 138 ft back of the mill, has a knife 42 in. wide and a stroke of 12 in. The eccentric shaft is 28 in. in diameter. The capacity of the shear is 3,500,000 lb, and it will cut a hot duralumin bloom 10 by 36 in. The depressing table is balanced by a hydraulic cylinder and is on the same system as the top roll balance of the mill.

The main drive of the mill is by a motor built by Allis-Chalmers Manufacturing Company that operates at constant torque, 1,200,000 ft-lb, from 0 to 50 rpm, and at constant power from 50 to 120 rpm. It operates on a nominal voltage of 600. The current for the motor is furnished by two direct-current generators with a combined capacity of 6600 amp at 600 v. They are driven at 507 rpm by a 4000-hp, three-phase induction motor operating at 6600 v. This motor is started by means of a liquid slip regulator. The flywheel is of the built-up plate type with no hole in the center, as it is supported on two flanges. It weighs

80,000 lb, is 16 ft in diameter, and has a rim velocity of 25,500 fpm.

The lubrication of all the bearings of the motor and motor-generator set is by circulating oil, filtered and cooled. The bearings are equipped with thermostats which shut down the motor-generator set if the temperature rises to a dangerous degree. A drop in oil pressure will do the same thing.

Structural Mill

The structural mill consists of three 3-high stands 26 by 60 in. and one 2-high stand 26 by 48 in. On each side of the mill are one traveling tilting table and one trailer table. Provisions have been made to roll lengths up to 135 ft. Duplicate tables can be added when production warrants.

The mill is driven by a 2000-hp, direct-current, variable-speed motor operating at 230 to 460 rpm through a herringbone reduction gear with a ratio of 4.60 to 1. The rolling speeds are from 360 to 720 fpm. The gear housing is arranged so that an additional motor and pinion may be installed opposite the present one, thus doubling the driving power without dismantling the drive.

Current for the mill motor is furnished by a motor-generator set of 1600 kw capacity, the motor of which is of the synchronous type, operating at 6600 v. In this motor room there are two 750-kw motor-generator sets which furnish direct current for all the auxiliary motors in this and the blooming mill.

Blooms are handled from the blooming mill on narrow-gage cars and gasoline tractors with rubber tires. The blooms are heated in an oil-fired, chain-conveyor type of furnace operating at a temperature range of 700 to 950 F. At the discharge end of the furnace the unloading device lifts the bloom clear of the chains and deposits it on the mill-approach roller table. The rollers in this table are of the internal-motor type, operating at 25 cycles, and are not of variable speed. The run-out table from the finishing stand of the mill is equipped with rollers of the same type, but since it is desirable to have them operate at variable speeds to coincide with those of the mill, current for them is furnished by a motor-generator set, the motor of which is a variable-speed, direct-current motor, the speed of which controls the cycles of the current furnished by the alternating-current generator and hence the speed of the motor rollers. This table carries the bar to a saw and a gag press, where ends are cropped and straightening done, where necessary to have the bar in proper shape to enter the heat-treating furnace. After the cropping and straightening operation, the bar is carried by a transfer table to the heat-treating-furnace car.

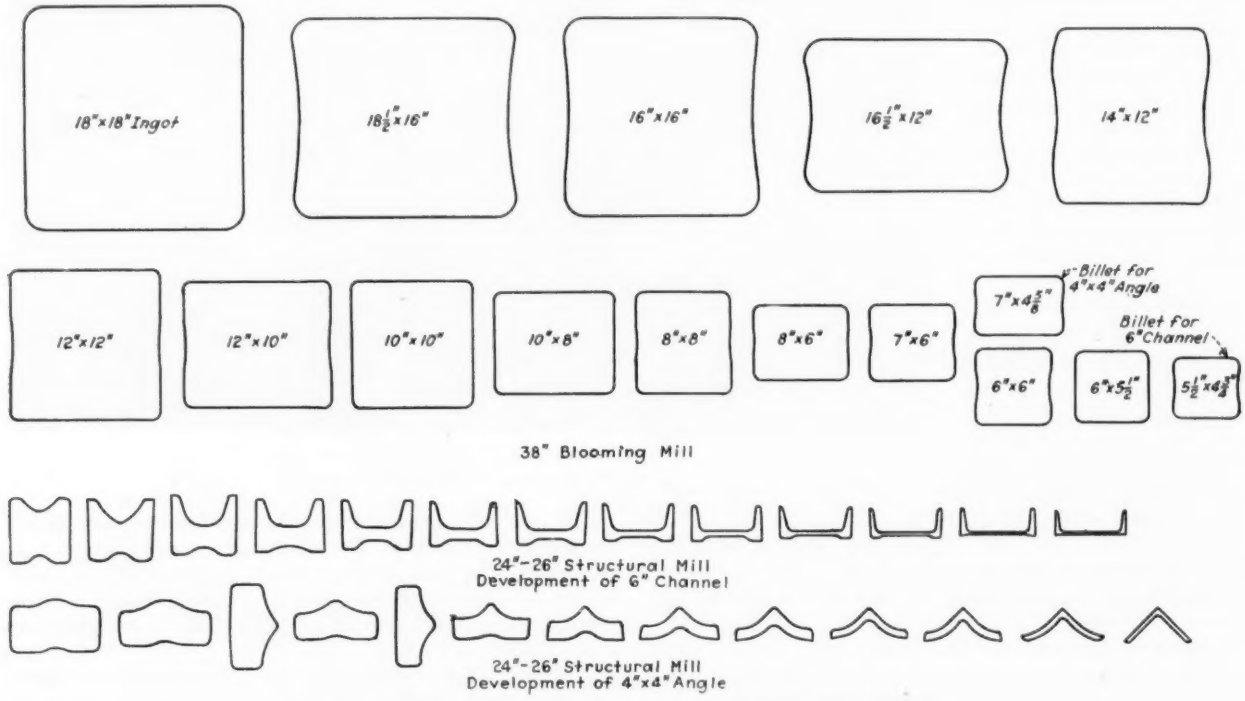

Fig. 4 Diagrams of Bloomer and Shape Mill Roll Passes
(These range from an 18 by 18-in. ingot, a 4 by 4-in. angle, and a 6-in. channel.)

Fig. 4 shows the bloomer and shape mill roll passes, from an 18 by 18-in. ingot, a 4 by 4-in. angle, and a 6-in. channel.

Heat Treating

In the heat treating of aluminum alloys there are two very important requirements: first, close control of furnace temperature, about 950 F, and second, quenching must take place in as short a time as possible when the alloy is withdrawn from the furnace. On account of the first requirement, it was decided to use an electric furnace, and the one constructed is the largest of its kind ever installed. It is 93 ft long and 20 ft wide. The heating elements are of the cast-grid, metallic-resistor type. The furnace is divided into 27 zones, and the temperature of each zone is separately controlled by an automatic temperature regulator. Pyrometric equipment is installed to indicate and record the temperature in each zone. A temperature differential of $\pm 7\frac{1}{2}$ deg F is maintained in the working area of the furnace, insuring uniformity of heating throughout the length of the piece being heated.

The heat-treating car is of a special type, having 16 pedestals on which the bar rests. This car enters the furnace through a door at the right of the furnace end. The shuffleboard arms in the furnace lift the bar from the pedestals, and the car is immediately withdrawn from the furnace. During the time in which the bar is carried across the furnace by the shuffleboard

arrangement, it is brought up to heat-treating temperature, and is finally discharged on a roller table, which carries it through the quenching chamber, shown in the lower right-hand corner of Fig. 5. Here quenching is accomplished by a series of high-pressure water sprays, as the bar comes out of the furnace. This system of quenching was adopted after a careful study of all available methods. While it is not as rapid as tank quenching, it is entirely satisfactory and much cheaper to install and is less complicated to operate than the tank method. As the bar leaves the quenching chamber, it is carried on a transfer table to the straightening press or roll straightener. After the bar is straightened, it is transferred once more to the run-out table, which carries it to the stock pile or the loading platform.

Certain aluminum alloys must be "aged" after heat treating to bring out their maximum physical properties. This aging is accomplished by soaking at temperatures ranging from 250 F to 340 F, and the time required is from 24 to 36 hr. In order to secure adequate production, this aging is done in large batches, as aging furnaces are simple in design and construction and comparatively inexpensive to build. In this mill the aging furnace is large enough to hold two standard-gage railway cars loaded with bars up to 90 ft in length. The furnace is heated by steam, and the air in the furnace is circulated by overhead fans, insuring rapid and uniform heating throughout.

Characteristics of Aluminum-Alloy Manufacture

There are many details of practice in the rolling of aluminum and its alloys that are not generally present in the practices with other metals. It might be of interest to mention a few of the more important points in which aluminum differs from other metals in regard to handling during the process of rolling shapes.

The most widely used strong aluminum alloys contain about 4 per cent copper. When the ingot freezes, a high-copper alloy, still molten, is forced out to the surface of the ingot by the pressure of the freezing crystals within. This process of liquation results in a network, which sometimes contains as high as 35 per cent copper, being distributed more or less generally over the surface of the ingot. This alloy is extremely hard, and while it is present in very small quantities compared to the weight of the ingot, it will cause considerable grief if not removed. Scalping all four sides of the ingot is resorted to, and this may be accomplished by any one of several machines, planers, boring mills, or milling machines, whichever machine seems to be best suited for the particular size and shape of the ingot that is being used.

The operation in the soaking pit is a little more involved than just a mere heating up to the rolling temperature. A metallurgical change must take place, and this change requires much longer time than bringing the ingot to temperature. In fact, sometimes it is desirable to soak the ingot for a considerable period above the best rolling temperature. In this case the ingot must be cooled carefully after soaking in order to bring it down to the rolling temperature and still have its temperature uniform throughout its mass. This complicated procedure cuts down pit capacity, necessitates expensive heat-control equipment, and increases production cost.

The hot ingot on the mill-approach table, with its four sides carefully machined, and found to be at the correct rolling temperature by the last pyrometer test, appears to be all ready for the job of rolling, which should be carried on quickly and without trouble. But the interior of the ingot is not visible. It is made up of large crystals, which must be broken down carefully by a few light passes on the mill. The metal is brittle in the cast state, and ingot cracking is likely to occur. There is also a marked tendency for the ingot to twist and curl after a few passes on the mill. Sticking to the rolls, which is very likely to occur with aluminum, is prevented by the use of a flooding system of oil solution. This solution must be filtered and cooled continuously, which necessitates a costly installation of tanks, filters, coolers, and pumps. Rolling must be done without marring the surface of the metal, which means that main rolls, manipulator bars, table rollers, guides, and aprons must be kept in perfect condition all the time.

Shearing the blooms and billets does not present any particular difficulties, but here again every precaution must be taken against marring the surface of the metal. It is much safer to pick up the bloom back of the shear than to push it off the table on slides or let it fall on the car that carries it out of the mill. And of course it cannot be picked up with a magnet. Very little is possible in the way of reconditioning bloom surfaces by chipping or filing. In some cases blooms that might otherwise have to be scrapped are scalped in order to reclaim them.

Heating blooms for the structural mill presents no particular difficulties if proper temperature control of the heating furnace is secured. The actual rolling of the shape is not attended with some of the difficulties met with on the blooming mill. The metal is not in the cast condition, and hence there is less danger of cracking, and high rolling speeds may be used if sufficient power is available. However, there is still a tendency for the metal to twist in the passes, and stickiness of the hot aluminum still gives trouble. Guides must be in perfect condition and well lubricated. Roll grooves must be smooth and also well greased. It is difficult to force aluminum up into roll grooves, and once there, it is equally difficult to get it out again.

Power Required to Roll Aluminum

On account of the comparatively short time that suitable equipment has been available, tests made to find the power required to roll aluminum alloys are still very incomplete. On account of the numerous alloys being used and the large variety

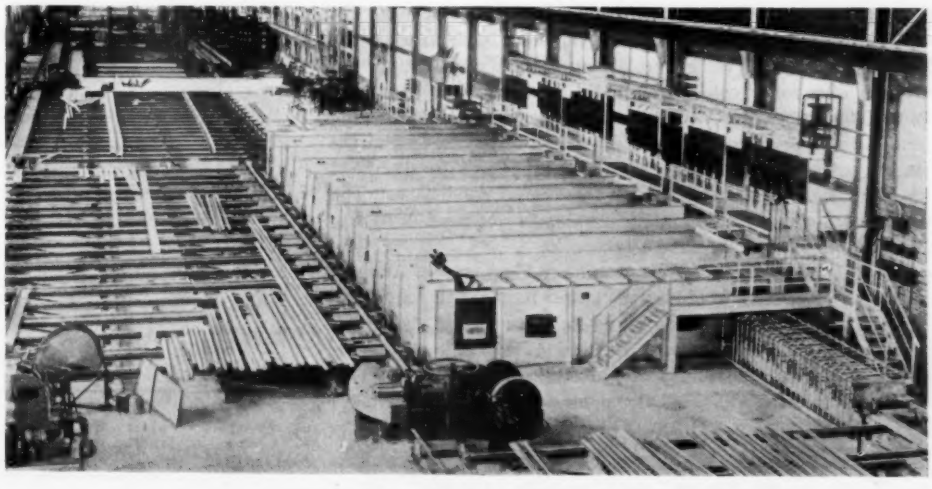

Fig. 5 Discharge End of Electric Heat-Treating Furnace
(This will handle shapes up to 90 ft in length.)

of sizes being rolled in small quantities, it will take several years to accumulate sufficient data to form the basis of any very definite conclusions regarding the power required for specific reductions in area and how the power is influenced by the many variables met with.

The reason that no tests were made before 1929 is that there were practically no mills used for rolling aluminum that were individually driven except some double-duo hot mills and small strip mills rolling foil. The former mills were not suitable for obtaining accurate power readings, and the foil mills were small, rolling only cold thin strip, so that the range of data possible to secure would be very limited.

During the rolling tests made at the Cleveland Works of the Bourne-Fuller Company, data were taken in order to ascertain, if possible, the actual power required to roll large alloy ingots and to find out the relative power required to roll aluminum and steel under the same conditions, each being rolled of course at its proper temperature. Unfortunately, only four aluminum-alloy ingots were available. Owing to the fact that the mill was set up for rolling steel and that the mill crew had never rolled aluminum, the results obtained were not conclusive. They did indicate, however, that high-strength aluminum alloys rolled at the correct

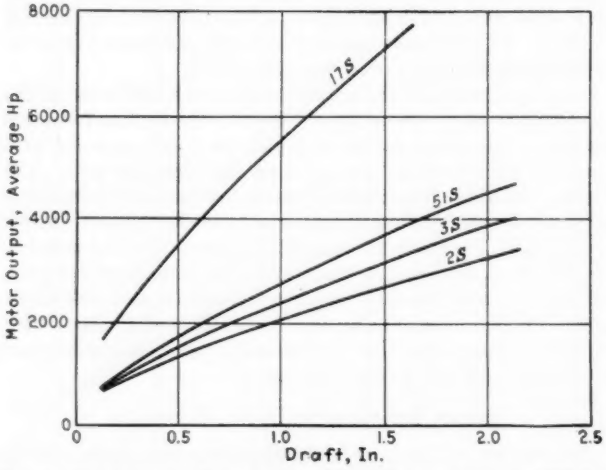

FIG. 6 HORSEPOWER REQUIREMENTS FOR REDUCTIONS ON 1500-LB PLATE INGOTS

temperature required about 50 per cent more power than open-hearth steel rolled at its proper temperature.

In 1929 the author made some rolling tests in Switzerland on three-high strip mills using pure aluminum and duralumin, both of which were rolled cold. The metal used was 12 in. wide and about 0.06 in. gage. Various reductions were tried, ranging from 25 to 70 per cent. The object of the tests was to find the relative power required to roll pure aluminum and duralumin at the same gage and under exactly the same conditions. The results obtained indicated that duralumin required 2.70 hp, where the pure metal required 1 hp.

During 1931 engineers of the Aluminum Company of America made a series of tests to obtain the power required to roll aluminum alloy slabs and plates on an 84-in. plate mill at the Alcoa, Tenn., works of that company. In the data that follow reference is made to four different alloys, designated as 2S, 3S, 51S, and 17S. Typical compositions of these alloys, by percentages, are:

	Cu	Mn	Mg	Si	Fe	Al
2S.....	0.08	....	....	0.15	0.40	99.37
3S.....	0.07	1.25	....	0.13	0.38	98.17
51S.....	0.08	....	0.60	1.00	0.35	97.97
17S.....	4.00	0.70	0.50	0.10	0.30	94.40

The tensile strengths of pure aluminum (2S) and various alloys are as follows (the point of 700 F having been selected as this represents the lower rolling-temperature range):

	At 75 F, lb per sq in.	At 700 F, lb per sq in.
2S.....	13,500	1850
3S.....	15,500	2900
51S.....	14,000	2000
17S.....	25,500	4300

These figures apply to rod instead of sheet, as no figures are available on sheet at the higher temperature. The 2S and 51S were rolled rod, and the other two were extruded. These figures are from "The Aluminum Industry," Edwards, Frary, and Jeffries.

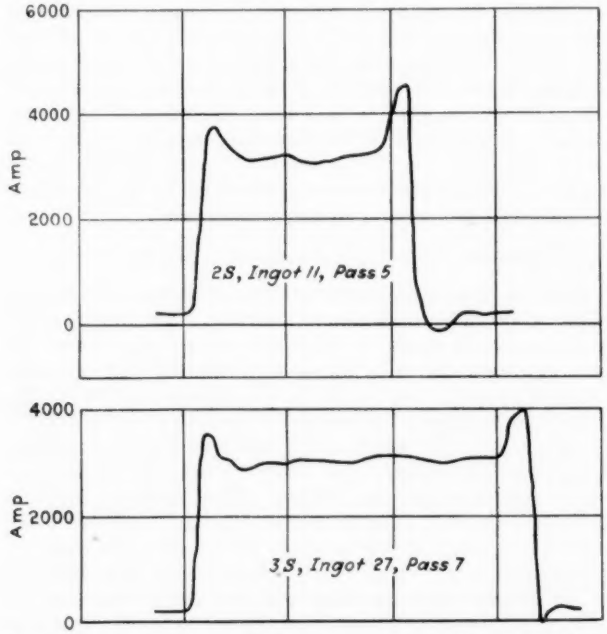

FIG. 7 TYPICAL AMPERE CURVES FOR AN 84-IN. THREE-HIGH PLATE MILL
(Rolling pure aluminum and a 1.25 per cent manganese alloy.)

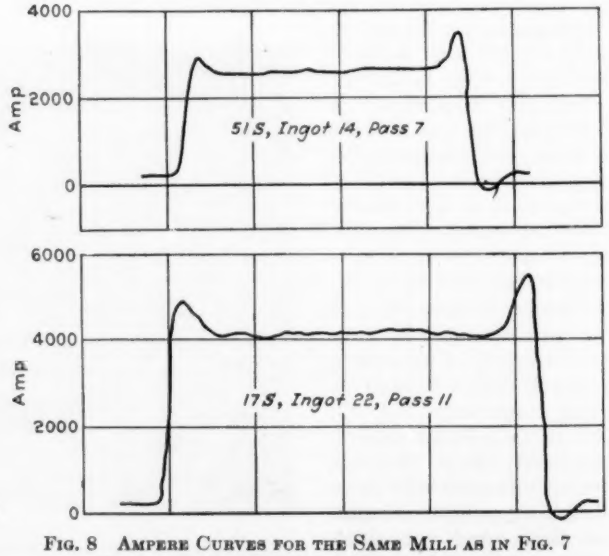

FIG. 8 AMPERE CURVES FOR THE SAME MILL AS IN FIG. 7
(Rolling a magnesium-silicon alloy and duralumin.)

The mill on which these power tests were made is driven by a 2000-hp, variable-speed, direct-current motor having a rated speed range of 165 to 330 rpm. This motor is geared to the mill through a reduction gear with a ratio of 6 to 1.

A two-element oscillograph was used to record amperes to the motor, and time was recorded by a jog in the ampere curve at 0.209-sec intervals. A McCollum-Peters telemeter pressure plug was used under one mill screw, and this was connected to the voltage element of the oscillograph and produced a curve representing pressure in exact time relation to the ampere curve.

Horsepower requirements for various reductions for the four alloys are shown in Fig. 6. These curves are based on reductions of about 25 per cent, the higher powers being obtained on the first passes. No widening passes were taken, and the width of the slab remained at 42 in. The ingots as started were 7 by 42 by 50 in. and weighed 1500 lb. The rolling speed was held at 230 fpm, and the ingot temperature were 850 F, which dropped down to about 700 F before the slab was finished. These curves show the average horsepower over the rolling pass, but the ampere curves from the oscillograph indicate peaks at the beginning and end of each pass. Typical curves for the various alloys are shown in Figs. 7 and 8. The peaks are from 0.25 to 0.50 sec duration, and their values vary from 125 to 140 per cent of the current during the rest of the rolling pass.

The investigations made at Alcoa verify the results of the tests made at the Bourne-Fuller Works, indicating that 17S alloy requires about 50 per cent more power than steel. However, 2S requires much less power than steel, possibly in the ratio of 6 to 10. The curves in Fig. 9 compare these two alloys with steel. The data for 2S and 17S were taken on 1500-lb plate ingots having the same dimensions as those mentioned. These ingots were rolled to $^3/_8$-in. plate on the 84-in. plate mill at a rolling speed of 230 fpm. The curve for steel is taken from a paper by H. A. Winne in *Iron and Steel Engineer*, June, 1932, and refers to an ingot $12^1/_2$ by 33 by 50 in., weighing 5700 lb, rolled to plate $^3/_8$ by $35^1/_2$ in. on a three-high mill having plain bearings.

A comparison of the power required to roll steel and 17S channels is made in Fig. 10. The information for the 17S curve was secured during a test made at the Massena Works of the Aluminum Company of America when an 8-in. channel was rolled from a $5^1/_2$ by $8^3/_4$-in. bloom on a three-high mill with plain bearings at a speed of 350 fpm. The steel curve is from the H. A. Winne article and refers to a 10-in. channel rolled from a $8^1/_2$ by 11-in. bloom on a three-high mill with plain bearings and a mill speed of 400 fpm.

When comparing power required to roll aluminum and steel, results are misleading unless the rolling temperatures are taken into consideration. The increase in power required, due to falling off in temperature during rolling, is quite different for the two metals. This relation is shown in Fig. 11. For 17S the increase in power required due to a decrease in temperature from 850 F to 700 F is in the neighborhood of 38 per cent, while for steel the power required at 1800 F is 100 per cent greater than that required at 2100 F. This indicates that while 17S at its normal rolling temperature requires more power than steel at its normal rolling temperature, the former may be rolled through a relatively wider range of temperature without serious increase in power and consequent stresses on rolling equipment. Results obtained from the tests on 17S previously mentioned as compared with results from various tests on steel indicate that while 17S at 700 F requires 50 per cent more power than steel at 2100 F, 17S at the same temperature requires 30 per cent less power than steel at 1900 F.

Extrusion

The first question that arises in regard to the extrusion of aluminum is why this process is used in preference to rolling. There are several answers to this question, each being in itself a logical reason why extrusion is resorted to. Suppose we classify these answers or reasons by products extruded in practice showing why extrusion is to be preferred over rolling or, in the case of tube blooms, over piercing.

It is hardly conceivable that even a mill devoted entirely to rolling structural shapes would be equipped with rolls for rolling all of the many shapes in their various sizes that are listed in the handbooks as standard products. But it is conceivable that customers will buy what they need or, in some cases, what they think they need, without giving much thought to the question of available rolls on which to roll their requirements. No matter what the reasons may be, producers will be offered business for

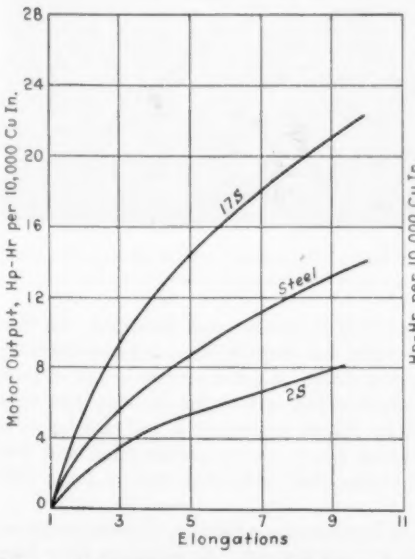

Fig. 9 Comparison of Power Required to Roll Pure Aluminum, Duralumin, and Steel Plate on a Three-High Plate Mill With Plain Bearings

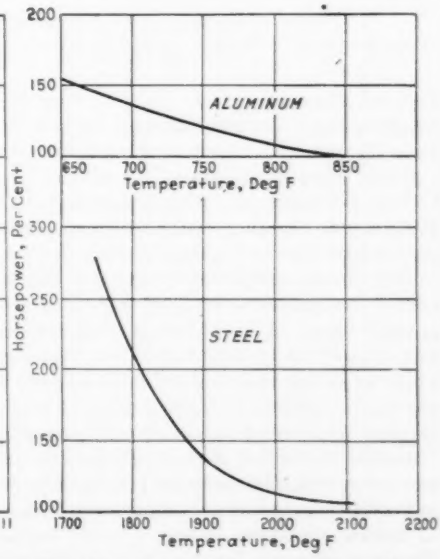

Fig. 11 Curves Showing How Power Varies With Temperature of the Metal Being Rolled, in This Case Steel and Duralumin

standard shapes for which they have no rolls available, and in the case of aluminum alloys, the way out is to turn to extrusion. It is a much simpler problem to provide extrusion tools for a new section than to provide rolls for a shape mill, as the cost will be less than a tenth of that required for rolls and the time required will be days instead of weeks.

The question of special shapes is of extreme importance, as in this classification falls a large percentage of the extruded aluminum-alloy business. These special shapes may be odd sizes of

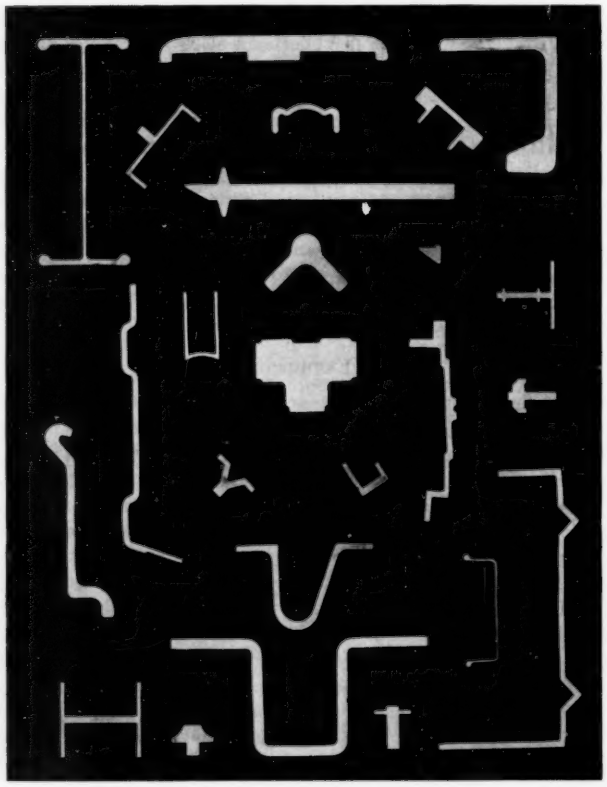

FIG. 12 MISCELLANEOUS EXTRUDED SHAPES
(These are typical of the sections used for aircraft, bus, and truck bodies and the like.)

so-called standard sections or they may be sections that are nearly standard but are changed just a trifle to suit the designer's necessity or whim. Some of the sections shown in Fig. 12 fall into this latter classification; for instance, the I-beam with the bulbs at the extremities of the flanges and the angle strengthened at the point. Another class of special shapes is that which covers the sections used in building construction for trim. These are usually of such complicated shape that they could not be rolled even if the quantities involved warranted the purchase of rolls to make them. A few of such sections are illustrated in Fig. 13, and an assembly showing how these sections go together to form a pilaster joining two window frames is shown in Fig. 14. Generally these sections are thin and carry no loads whatever. They are used for covering and ornamental purposes.

Another important class of extruded products includes those sections on which further work is to be done, such as tube blooms and sheet slabs as well as rectangular billets. Today practically all drawn aluminum tubing is made from extruded blooms. The principal reason for this is that the bloom that goes on to the draw or push bench must be as nearly perfect in finish and dimensions as it is possible to make it. Extrusion seems to be the only practical method for obtaining these results. It is possible to pierce aluminum-alloy billets, and this practice was followed for several years, but was abandoned for the extrusion process principally for the reason that the extruded blooms were much more nearly perfect, resulting in lower scrap losses and better finished product. Extruded blooms may also be made in a larger variety of sizes than is possible on a piercing mill, thus relieving the draw bench of considerable work in reducing the area of the bloom. It was also common practice until within a very few years to make tubing from sheet circles, using a cupping press and hydraulic push bench to make the blooms, but this practice has also been discarded for the extrusion press. It is regular procedure today to extrude tube blooms as large as 12 in. in outside diameter with $^1/_2$-in. walls and as small as 1 in. in diameter, with a wall thickness of $^1/_{16}$ in.

The extrusion of sheet slabs may be accomplished without serious difficulty, but it is done only under exceptional circumstances. If a hot mill is convenient and in operation, rolled slabs are much less expensive, and of course can be rolled in sizes not possible by extrusion. Reports have been received from Europe of the extrusion of sheet slabs in tubular form. These tubes are slit and flattened for rolling. There seems to be nothing to recommend this process if a rolling mill is available for rolling hot ingots.

There is still another class of extruded products—those made from alloys that cannot be rolled. Certain aluminum-mag-

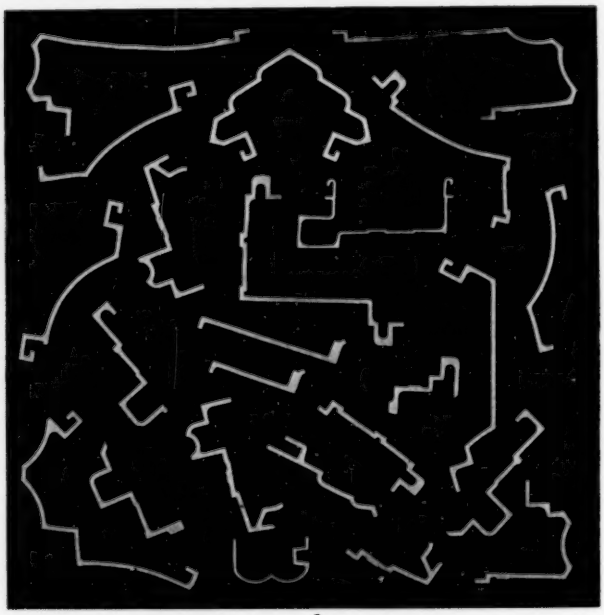

FIG. 13 EXTRUDED SHAPES USED FOR ARCHITECTURAL BEAUTY
(These sections are made thin and usually carry no stresses.)

nesium alloys are so brittle in the hot cast condition that they break up badly on rolling, but extrude without great difficulty. On account of its very desirable physical properties one of these alloys is used to a considerable extent for drawing fine wire. It has been found to be almost impossible to roll cast ingots of this alloy, so billets about $1^1/_2$ in. square are extruded, and then put on the rod mill, where they are rolled without great difficulty.

All extrusion is done from ingots extruded in the cast condition; in other words, they are not scalped. Experiments have been made to see if rolled blooms have any advantage over cast ingots for extrusion, but there seems to be nothing to be gained by their use. Extrusion is done hot, the temperatures used being the

same as for rolling the corresponding alloy, and there is evidence to show that power required for extrusion varies with the temperature of the metal in about the same way that the power required for rolling varies.

While it is true, as has been stated here, that certain alloys extrude with less difficulty than they roll, this is not true of all alloys. Pure aluminum rolls and extrudes more easily than any

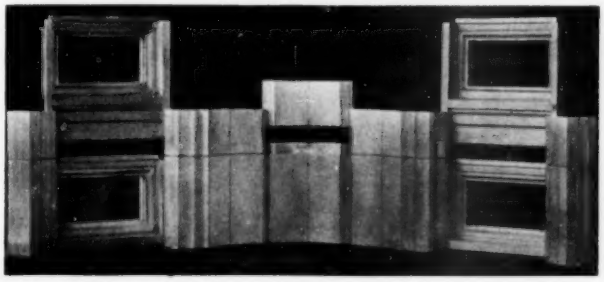

FIG. 14 AN ASSEMBLY OF EXTRUDED SHAPES INTO A PILASTER AND TWO WINDOW FRAMES

of its alloys. Those alloys of the duralumin class, containing about 4 per cent copper, require about three times as much power to roll as pure aluminum. While there are no definite data on the comparison of power required, if possible speed of extrusion be used as the measuring stick, then the duralumin-type alloys require ten times more power for extrusion than does pure aluminum. On the other hand, the alloys containing higher percentages of magnesium cannot be rolled at all, but extrude without serious difficulty.

In color and surface finish extruded products are quite superior to rolled shapes. This is very important where aluminum is used for decorative purposes, particularly for architectural work. There an alloy containing 5 per cent silicon is used for its desirable properties of color, strength, and resistance to corrosion.

Just what the immediate future will bring forward in the art of rolling and extrusion of aluminum alloys is hard to forecast. It does not seem probable that there will be much change as far as size of equipment and dimensions of product are concerned, except in the case of rolled shapes. Here there seems to be a tendency to go to sections as large as 15 in., where 10 in. is the largest used up to the present. As far as plate is concerned it would appear that the present equipment, which includes a 144-in. mill, will be large enough for some time to come. The same is true of extrusion, where the present equipment, which extrudes a 12-in. tube bloom, should be sufficient for all purposes for the present and the near future, at least. Progress during the next few years will more than likely be in new alloys with better physical properties and lower costs of production.

MAN-55-1

Progress in Management

INDUSTRY during the last year has had to face not only the problems that arise from the conditions brought about by business depression, but also those that come with any financial crisis. The year 1931 left a heritage of world economic disasters that commenced with the failure of the Austrian Credit Anstalt and spread throughout all Europe, affecting Germany and England, and that finally shook our own economic structure to its very foundations. The victory of the American dollar in June of this year marked the turning point in economic affairs, and reestablished, for the time being at least, business confidence to the extent that the administrators of business are now able to face the future with some degree of assurance that the worst of the financial storm has passed. Management has yet many crucial problems to solve before industry can again fall into step in the steady march of progress.

Management learned many valuable lessons in the depression of 1921, and it has the opportunity to learn many more out of the business depression and financial crisis of 1931 and 1932. The administration of business in a time of rising prices is not as difficult nor as fraught with danger as it is in a time of falling prices. Business executives have followed in the past the fetish of volume and mass production, without regard to the ability of the consuming public to absorb the ever-increasing flow of goods that the highly specialized wheels of industry are prepared to turn forth. It is now evident that to artificially stimulate business to bring in volume, for the purpose of reducing costs and supposedly for increasing profits, merely puts off the evil day of reckoning. Industry in the future must organize itself and be prepared to supply that quantity of products, first, which can be economically distributed and, second, which can be economically produced. In fact, all phases of business activity must be balanced and equally well managed if a state of economic equilibrium is ever to be attained.

The day of competition is past. Industry must learn how to cooperate. There is just so much volume of business for every one when the flow of goods and money or credit is normal. Plants must be built or reorganized with this in view. Large expenditures of capital in productive equipment of a specialized nature are to be avoided. Volume can no longer be sought as the road to profits. Profits will come through the recognition that there is a certain normal volume of goods which at any time can be consumed, and that productive facilities for single-shift operation will be based on this quantity. Temporary increases and decreases in business activity can then be adjusted for, without serious dislocation, and productive capital can be much more efficiently employed.

Management, heretofore, has been too greatly concerned with the evolution of methods, systems, and mechanisms. The techniques of management must now be brought into a greater state of simplicity, flexibility, and sensitiveness if the hoped-for stability of business is ever to be gained. More than ever the management of industry must be entrusted to men of creative ability and leadership, with judgment and foresight, who will be able to sense the natural change in economic conditions and adjust the course of business to maintain a more stable situation, provide adequate opportunities for employment, and return a reasonable profit from all operations.

At least it is encouraging to note that throughout this country there is a growing appreciation of the importance to industry of an enlightened public opinion on manufacturing, social, and economic matters. In particular there is a broadening interest among engineers in the fields of economics and distribution. Furthermore, the attitude toward labor-saving machinery is changing in that it should be employed to save labor rather to increase capacity and production; that is, to reap the benefits of greater leisure through shorter hours. There is also the recognition of the advantages of versatile employees and supervisors which arises as a corollary to slower mechanization in industry to maintain greater flexibility. Likewise, there is evidence of an increase in the caliber of those in supervisory positions in industry by the employing of high-school- and college-trained men and women. Even at this time when the greatest economy must be practiced there is an ever-increasing recognition of the necessity for organized research into marketing, new products, production methods, and business methods. Studies are also being made of the costs of distribution and of production with particular regard to overhead costs in order to detect the characteristics of the fundamental cost structure peculiar to individual plants.

Developments in the Marketing Field

The past year, having been one of extreme business depression, has demanded more attention than ever before to the study of marketing. Furthermore, existing conditions have enabled those who gave proper attention to this subject to prove with satisfaction to themselves and to others, not only the value, but also the absolute necessity of thorough and continued study of this important factor of business.

In addition to materially decreased volume, prices generally were lower; as a result, the manufacturer was confronted temporarily with a prohibitive marketing cost, a situation which required prompt attention and careful analysis. Among many manufacturers this situation was realized and dealt with successfully.

Such manufacturers, including many nationally known companies, have succeeded, not because their problem was simpler, but because they took such steps as were necessary at the proper time.

Sales personnel, both direct and indirect, was reduced, particular attention was concentrated on competitive situations, and territories were carefully studied to eliminate those sections expensive to cover. Information available from advertising media was utilized to take full advantage of the best markets. Through careful study, better coverage per salesman was effected and greater thought given to allocating individual sales effort, eliminating certain difficult customers whose business was previously sought.

One large food company falling under this category has succeeded in keeping its percentage of marketing expense within 1 per cent of that of the previous year. Some motor-car manufacturers and certain utilities show results almost as interesting.

On the other hand, many companies have had a most difficult situation. Business at times had to be refused due to unsatisfactory credits. It was found in some quarters that expense reductions were immediately followed by decreased income. Reconstructed budgets were continually found short on the income side, resulting in continued unbalanced situations, so that in many cases all profits and assets were sacrificed, with receiver-

Presented at the third session of the Management Division, Thursday morning, December 8, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Personnel of the Executive Committee of the Management Division for 1932: Fairfield E. Raymond, Chairman; George W. Kelsey, Secretary; William B. Ferguson, Vice-Chairman; Charles W. Lytle, John R. Shea, Joseph A. Piacitelli.

ships resulting and many companies going into the hands of the banks or of other creditors.

Some of these results were inevitable due to lack of sufficient reserves, insufficient purchasing power, or lack of demand for the product; others were due to delay in action; and some were due to failure to properly follow out the basic principles of marketing in what has become a buyer's market.

The machinery industry has been severely hurt; some sales organizations have been almost sacrificed; orders have in many cases been taken at less than cost; and terrific losses have been sustained.

Other industries, sugar for example, awaiting the outcome of a government suit, have just marked time.

Certain farm-machinery manufacturers have shown ingenuity in stimulating sales by agreeing to accept payments for some items on the basis of corn and wheat at certain fixed prices above those prevailing at the time.

Several outstanding developments in marketing have occurred during the year, such as:

(1) Development of a general sales consciousness among factory and office personnel of companies as well as stockholders, with definite material assistance to their respective sales departments
(2) Growing recognition of necessity for research into business methods and marketing
(3) Better study of consumer requirements—that is, determination of products most suitable for customers' use and providing the least sales resistance
(4) Greater utilization of data furnished by agencies, associations of manufacturers, marketing associations, chambers of commerce, etc. to determine the most lucrative territories for various products
(5) Continued active interest of bankers and financial institutions in assisting industrials to develop improved marketing methods
(6) Government activities for collection of marketing data, such as the Louisville grocery survey, national drug survey at St. Louis, retail credit survey, study of causes of business failures and bankruptcies of individuals in New Jersey.

Many industrials and even industries have used the services of trained economists, engineers, and marketing counselors effectively in revising their sales policies and organizations.

An interesting situation existed in one representative concern where over 90 per cent of the business was obtained from less than 15 per cent of its customers. A careful study developed a change in policy of handling the other 85 per cent approaching that of the mail-order house, which considerably reduced total expense and improved the business from the smaller customers.

Margins previously existing for marketing have so diminished that little remains available for errors or guesswork; hence the necessity for even more exacting marketing efforts in the future.

Stabilization of Employment

In March, 1932, there were between eight and nine million unemployed in this country, and it is doubtful that any material reduction has taken place since then. The seriousness of this situation has brought home the need for a better planning process such as will provide guidance and control over our economic life and lessen the likelihood of devastating and socially harmful unemployment. As a result, five official and semi-official as well as many other private proposals have been presented, all aiming at a more stabilized economy, which in turn may be translated into stabilized employment. These "plans" do not reflect the desire to imitate Russia, but rather the eagerness to develop our own American planning based on voluntary cooperation, assisted by the official establishment of a National Planning Organization and the amendment or even repeal of the American anti-trust laws. The proposals differ largely in the matter of control. Some would intrust it to the state, others to public bodies, others[1] to industry itself; some advocate an advisory control, while others a real supervisory control.

Aside from the foregoing proposals, the United States Chamber of Commerce offers a stabilization program for the "continuity of business and employment," with long-time measures similar to those of other plans. Immediate measures are also proposed for meeting the problem of unemployment. These include centralized local organization following the lines of the so-called Rochester plan; central registration of workers seeking employment; and planning and execution of public works. The directorate of this body recently approved the "40-hour week," which is in line with its stabilization program.

A study of the causes of seasonal fluctuations in business was made by a group of New England business men, and attempts toward stabilization of employment for the individual worker are summarized by Edwin S. Smith as follows:

1 Training of versatile workers, permitting transfer from less active to more active operations
2 Reluctance of worker to transfer
3 Maintenance of usual earnings when on temporary job
4 Transferring between industries to meet seasonal peaks that do not occur at the same time
5 Part-time employment
6 Shortening working hours.

With regard to this last item a recent survey in 77 different industries involving nearly 38,000 establishments and affecting approximately 4,000,000 showed that 5.6 per cent of all the employees covered in the study were on a permanent five-day-week basis. As far as the percentage of workers on the five-day-week basis is concerned, the automobile industry leads, with 44.3 per cent of the employees in the establishment reporting working on that basis. It is followed by radio, dyeing and finishing textiles, and aircraft industries. Specific information has been gathered from 50 companies regarding their operation of the five-day week, particularly relating to the use of skeleton crews on the sixth day. Of the 29 companies using skeleton crews three run a staggered system whereby every one in the office is out one-half day some time during the week, but at least half of the personnel is on duty at all times.

Thoughtful consideration is being given to the adaptation of the six-hour day to industrial operation. It has already been put to the test by a few companies that have considered the present an opportune time for experimentation. As a fine example of this, the Owens Illinois Glass Company restored its entire working force to employment by operating four six-hour shifts instead of three eight-hour shifts. Of the 318 companies reporting in a survey of what is happening to office working hours, 188 have made no change, 116 have decreased the hours, 4 have lengthened them, and 10 have special plans in some departments. Of those reducing working hours, 17 consider the change a permanent one, 32 are undecided whether the change is permanent or not, 37 consider it a temporary emergency, and 30 have made the change for the summer only. About 80 per cent of those reducing working hours have done so by discontinuing Saturday work. The pay in these cases has been reduced proportionately.

Legal steps have been taken in some states to provide for unemployment insurance that will serve for the purposes of both

[1] See "American Planning in the Words of Its Promoters," Hugo Haan.

relief and of an incentive for regularization. Wisconsin's Unemployment Reserves and Compensation Act compels employers to establish "systems of unemployment compensation," if they have not already voluntarily done so, by June 1, 1933. Similar measures are being considered by Indiana, Ohio, and Michigan.

In view of the legislation already enacted in Wisconsin and under contemplation in other states providing for the establishment of funds for unemployment relief, a committee appointed by the National Electrical Manufacturers Association to consider the plan presented by Gerard Swope has given its first attention to this feature of his proposal. The committee proposes a Nema mutual unemployment benefit plan which includes all employees that have served 12 consecutive months.

Accounting and Finance

During the boom period of 1929, working capital was frequently diverted to fixed assets for new equipment, plant extensions, and the like. This was subsequently replaced, as volume transactions made the need of it apparent, by bank loans. Then the business tide turned, and those bank loans either were a decided embarrassment or an actual menace in too many cases. Similarly, high bonded indebtedness, too high a proportion of borrowed to owned capital, particularly in industrial enterprises, has proved to be the *bête noire* of many boards of directors.

There was a feeling at one time that if the market for preferred or common stocks was unfavorable and the discount for financing too high and that if the bond market was good, it was just as satisfactory to finance with bonds, not recognizing what the ultimate effect might be or even contemplating the possibility of earnings shrunk below the fixed charges on capital.

Serious consideration is being given to the appropriate value to be assigned to assets. They have been revalued in the light of present conditions and possible future use, surplus and obsolete assets have been written off in many cases, and the surplus account at least partially reestablished by scaling down the stock and restating the capital in a number of instances. The published statements of many of the well-known companies in the country reveal this process as going on.

It is evident that industrial managements from now on will give more thought to the character of their financial structure, its set-up, and what the relationships of the balance-sheet items really mean.

A change has taken place in the use of budgets, and the technique has improved. With sales forecasts becoming obsolete by the time they were made, during the most violent period of the business recession, a means had to be sought that would regulate and control operating expenses more closely than heretofore. Therefore the accounting statistics were utilized as a basis to predetermine the fundamental relationships of non-variable, variable, and semi-variable expenses to production of varying rates. Similar studies applied to the distribution and general expenses determined their fundamental relationships to varying sales volumes or other suitable bases. This permitted the establishment of budgets monthly in advance, on a ratio basis and adjusted to the immediate future program.

Standard costs for predetermined steps or ranges in production were similarly established, and more attention has been paid to marketing and distribution expense accounting. The accounts were thus used to predetermine goals, as set forth by the budgets to furnish the basis for establishing standard costs and standard expense relationships rather than a source of recorded history when it is usually too late to do anything about it.

More and more efforts have been made during this period of subnormal business activity to mechanize accounting operations to the fullest economical extent, to simplify the procedure, to eliminate useless forms and reports and to consolidate the methods wherever practicable, and so utilize the accounting methods as to permit the establishment of and attainment of a predetermined goal, even if these goals were set up for comparatively short periods.

Plant Layout

The prolonged business depression has in some cases accelerated plant rearrangement. Many of the larger industries are changing from the functional type of manufacture to the unit type where a product is largely made complete in one department or by one group of machines. Micro-motion study and time studies have pointed toward a more intensive correlation of machines, which in turn has affected plant and building layout arrangement.

Further applications have been made in the use of artificial lighting and air conditioning, largely in connection with special processes where direct economies could be obtained.

Equipment

One of the outstanding things pointed out by this depression is the fact that most industries are overequipped from the standpoint of taking care of a normal growth in business. In the previous depression the outstanding fault was one of large inventories of raw materials and work in process; in this depression it is plant investment, including grounds, buildings, and machinery. More sound, long-termed predictions and planning for future growth must be devised in order to hold such investment to a normal figure.

In the development of new and improved machines a greater application of ways and means for reducing noise has been effected and improved devices have been made for the measurement of such noise.

A wider application has been made of hydraulic devices in the movement of machine elements, such as on heavy punch presses and drill presses.

Machines used in processes resulting in dust, etc. have until recently been exhausted by separate duct systems; self-contained units are now being made a part of such machine units, which together with individual motor drives make such equipment complete.

Manufacturing Processes

Most manufacturers have directed their engineering effort almost exclusively to the design of new products and their production on a low cost basis, using existing machines and processes, and as a result the last year has shown a minimum of development in the manufacturing processes field, outside of further extension of the use of tungsten and tantalum carbide and other improved cutting materials. In this connection equipment has been developed which accurately measures the force exerted on a cutting tool, and data obtained in this manner should aid in the further application of these materials and also in the redesign of machine tools in order to use them at their maximum efficiency.

There have been further refinements in the application of optical and X-ray methods of inspection of material for defects, and greater accuracies have been obtained in the gaging of parts by improved electrical and mechanical devices.

The use of lighter metal alloys is finding an ever-increasing application in industry and is bringing with it a decided change in processes.

Future product design and process development are being influenced by new plastic molding compounds whereby a wide variety of permanent colors may be obtained.

Drying processes have been aided mechanically, and as a result both the direct cost and the investment in material in process have been reduced.

Maintenance

Increased recognition has come to the function of maintenance, particularly in its relation to unit cost of product. Such recognition takes account of its—

(*a*) bearing upon indirect costs
(*b*) responsibility for prevention of breakdown and shutdown losses
(*c*) operation of plant and facilities at lowest cost for power, transmission, heating, lighting, and similar services
(*d*) strategic position in making observations as to equipment performance.

Progress has been made in the application of wage incentives and in task standardization. For example, the plant engineer of a company of note and considerable size has broken down and charted the inspection, testing, and repairing details in connection with all important equipment and has his operatives perform their work constantly by these charts. The maintenance department is conducted on the wage incentive basis.

Cost accounting, as it applies to maintenance, has been scrutinized, looking toward isolation and simplification. In the plant referred to, the cost-accounting method is being revised to be operated for maintenance as directly as is the function itself.

Acceptance of the practice of budgeting expenditures has increased in spite of inherent difficulties. The plant engineer of a manufacturer expending annually more than $450,000 for maintenance reorganized the maintenance department to insure centralized control and positive operation on a budget and schedule basis.

Much thought and discussion have been given to organization by personnel and duties for efficient and economical conduct of maintenance. Intense interest has been shown.

Production Control

There has been little significant progress during the last year in production control due largely to the lack of orders. For the most part the trend has been decidedly toward simplification and flexibility. What progress has been made has come chiefly through the results of cost analysis and the discarding of those methods that become uneconomical and unwieldy when applied to the markedly reduced operating schedules with which industry has had to contend. The trend toward "product production" is characteristic of the times, as the organization of the processes of manufacture according to products eliminates much of the old-time routines of production control, with its planning, scheduling, routing, and dispatching. A production budget for each manufacturing period takes the place in such instances of the continuous attention which had to be paid to the maintenance of production schedules.

Material Control

The conservation of material in manufacturing processes has been greatly aided by further extension of the use of raw-material specifications, improvements in tooling methods, and (what is most important) a more exact accounting control of actual wastes as they occur and the reductions of such waste by carefully planned intensive campaigns. In such cases the operator who is directly responsible for each step in the process has contributed greatly to the elimination of waste once he has realized the full significance from a dollars and cents standpoint of the loss and how such losses may be controlled.

Safety

Industrial accidents have generally decreased. This is due largely to reduced personnel. The careless workers have been weeded out, while the most efficient remain. In the paper and pulp industry lost-time accidents in 125 mills were reduced 19 per cent from 1930, while the number of days lost were 25 per cent lower in 1931 than in 1930.

Job Standardization

The depression has not lessened the amount of "motion and time study" as much as might have been expected. The necessity for reducing all costs and for getting out improved products has, in fact, advanced this work in many instances. In other instances where this work has been less essential than economy in overhead, curtailments have occurred, but in many of these cases the men, because of their training in analysis, have been transferred to effect other economies, and in a few instances such analysts have been lent to customer companies for the purpose of studying equipment from the user's point of view. This latter innovation has not only helped customers, but has resulted in equipment improvement and in some new business for the equipment makers.

The most outstanding development is, however, the continued extension of interest in micro-motion as a means of training any job analysts. Allen Mogensen, through "Factory and Industrial Management," and now through his new book, "Common Sense in Motion and Time Study," has succeeded in arousing company after company, while David B. Porter, through New York University, has succeeded in enrolling numerous company men for this training by means of night classes. Men so trained are able to make use of the principles of micro-motion without using the measuring technique originally thought necessary for micro-motion. What time measuring is necessary is done with the stop watch; hence the term "compromise method."[3] The results of this compromise procedure are infinitely superior to the best results of ordinary stop-watch procedure, and the opportunities are greatly extended over those of the full micro-motion procedure. Finally, there is a movement on foot to improve the definitions of the therbligs which has long been needed.

Wage Rates

The almost universal reduction in wage rates which has come during the last year and a half has led some to think that the American high-wage theory has been discountenanced. Nothing is further from the truth. The general movement for reduction did not get under way until commodity prices had come down, so that it is only by reduced working time that there is any reduction in real wage rates. An early-summer survey of the N.I.C. Board covering 1718 American business concerns does report a 26.6 per cent decline in employment, to say nothing of part time and short time, but the average reduction in executive salaries, weighted to the number of persons affected, was only 14.9 per cent, that of other salaries 13.1 per cent, and wages 11.1 per cent. The worker's dollar was found to be worth 22.7 per cent more in May, 1932, than in September, 1929. Thus it is not a matter of paying less in real wage rate, but rather a matter of too little working time. When the latter is taken into account, there is an average reduction of 23.1 per cent for the real pay envelope. This is certainly bad, but it does not indicate any repudiation of the high-wage policy. In fact, a few employers, who could do so, have actually raised wage rates in order to help recovery. On the other hand, since those fortunate enough to have full time are now receiving more real wages than in 1929, it is possible that further reductions in rates might be justifiable, especially if recovery does not come promptly. The unprofitability of agriculture is in part due to high urban standards. Since the products of agriculture are priced by world

[3] See forthcoming revision of "Management's Handbook."

competition, they cannot be artificially raised in a single country. Thus if further reductions are made in urban wage rates, they will be made with the purpose of extending work opportunities, and if standards of living are lowered for full-time employees, they will be corrected as promptly as conditions of the whole permit.

Wage Incentives

When companies are particularly hard pressed, there is a temptation to do away with the extra financial incentive plans, and that is what has happened here and there. American employers have, however, learned that properly designed and correctly operated incentive plans pay for themselves. The more pressing the labor cost problem, the more is this true. The solution of unemployment does not lie in lax work habits. Furthermore, it takes time to develop correct work habits, to say nothing of dropping lax ones. The best-managed companies may have reduced the amount of "bonus," but they are not abandoning all "bonuses." It is a good time to revamp plans and to see that the best type of plan is applied to each kind of work. In short, employers are more particular about all such adjustments during depression than during times of easier profits. The chapter on this subject in the forthcoming revision of "Management's Handbook" should be helpful in making this readjustment.

Industrial Relations

The lack of stability in employment has made progress in some phases of personnel management rather difficult. However, the unemployment situation has brought about a wider interest in this field on the part of general executives.

Of the replies received by J. E. Walters from representative industrial and business concerns of the Middle West, nine companies have added new activities such as foreman training, relief-fund work, and unemployment pensions. Eighteen personnel departments have increased or decreased less than other departments of their companies, while only three have decreased more or discontinued. No records were found of any company that maintained relief activities for employees laid off during the depression of 1921. This in itself is indicative of a trend toward more humanism in industry. Another trend worth mentioning is that the smaller companies are becoming more personnel minded.

The Institute of Human Relations is conducting industrial investigations centering about a "total science" study of human problems of technological progress. The instance selected for the first investigation is the so-called "multiple loom or stretch out" system in the textile industry—the increase in number of looms or spinning frames tended by the individual operator. To date, studies of twelve[3] typical mills in the North and South have been completed. The work is being done by a staff headed by Prof. Elliott Dunlap Smith and supervised by a committee of scientists representing various fields.

Dr. E. K. Strong, of Stanford University, has devised a test known as the Strong vocational test, and has given it to a number of people in various occupations to discover range of interest. The student may then compare his interest pattern with those of the various occupations in which he is interested. Stevens Institute has set up a summer camp for high-school juniors and seniors in an attempt to measure quantitatively the interest of students through the methods developed by Johnson O'Connor and W. V. Bingham.

[3] Ten more than reported in previous publications.

Education

For the first time data are available as to the extent of industrial engineering education.[4] There were, in 1931, 35 engineering colleges in the United States giving full industrial engineering courses, 30 of which graduated that year 596 men. Four of these courses were too recently started to have graduates. The ratio of these graduates to business-school graduates is estimated at only 1 to 10, a proportion that is too small for normal conditions. Because of present conditions the graduates of 1931 and 1932 have not yet been absorbed, but industrial engineering graduates of earlier years have very largely retained their jobs, doing better in this than graduates from any other department of engineering. Recent meetings on both industrial engineering education and industrial training in the factory have indicated increased interest in these matters.

Research

Throughout this last year, when industry has been called upon to make most drastic retrenchments, it is of importance to note that there has been a point where the far-sighted executive has refused to curtail further the research activities of his enterprise. Many enterprises have weathered the effects of this depression chiefly through their reliance in research. Evidence of this is given in the report of the National Research Council which appeared this spring, covering data secured from some 400 companies representing 20 industries. Of these, 51.3 per cent increased their research expenditures in dollars in 1931 as compared with 1929, 18.7 per cent made no change, and 30 per cent decreased. Translated in percentage of sales, it is found that 75.3 per cent increased their research expenditures in percentage of sales in 1931 as compared with 1929, 15.7 per cent made no change, and 9 per cent found it necessary to decrease these expenditures. These figures, with slight variations, hold true of practically all of the industries. There has also come about a change in the emphasis of research. In 1928 a similar survey was made, and at that time the most important emphasis of research programs was in lowering production costs. Today the major emphasis of 37.7 per cent of the companies reporting was in the development of new products, 37 per cent in improvement of quality of existing products, and only 19.4 per cent in lowering production costs.

While the situation has undoubtedly changed materially in 1932, nevertheless where research expenditures were cut it was one of the last of the business aids to feel the pruning knife.

Aside from the imposing record of scientific research and engineering development, it is significant to note in the recently published report of the Business Research Council the extent of business and economic research being conducted by American colleges and universities. The research projects listed cover many aspects of finance, labor, marketing, production, transportation, public utilities, prices, business cycles, business management, economic history and geography, accounting, statistics, and business law, as well as many other topics of value to the business executive to a lesser degree. The report states that 108 institutions are conducting 620 research projects of this nature. Moreover, 80 series of statistical data are being continually compiled by these institutions on banking, securities, labor, wholesale and retail trade, foods, textiles, metals, lumber, real estate, buildings, power, automobiles, prices, and the like. Evidently there is a wealth of information being procured by these institutions which is of inestimable value to industry.

MAN-55-2

Ten Years' Progress in Management, 1923-1932

By LEON P. ALFORD,[1] NEW YORK, N. Y.

Industrial management has undergone a severe test in the decade 1923–1932 due to violent fluctuations in industrial activity and sharp contrasts in the results of operating performance. Despite these changes it has made steady progress. It has been extended to all human activities where work is done. It has contributed to the accelerated rate of industrial development of the first six years, and its principles and practices have withstood the decisive trial of the deep depression of the last three. As an outcome of its application, well-managed concerns have passed through this period of business recession better than all others; as a result of its progress, management is now firmly established as a function in industrial operation. An examination of the changes in trends of some 25 industrial-management developments supports this major finding.

THIS PAPER is the fourth of its kind to treat of the progress of industrial management for the attention of the members of The American Society of Mechanical Engineers. The first was a committee report of 1912 under the title, "The Present State of the Art of Industrial Management." The second, a paper of 1919, was on "The Status of Industrial Relations." The third, a paper of 1922, a review of ten years' progress, was founded on the report of 1912 and was titled "Ten Years' Progress in Management." This paper seeks to review the changes and progress of another period of ten years, the decade just closing. For its foundation it reaches back to the three preceding summaries.

[1] Vice-President, Ronald Publishing Company. Mem. A.S.M.E. Mr. Alford was born in Simsbury, Conn., on January 3, 1877. He was educated at the High School at Plainville, Conn., and Worcester Polytechnic Institute, obtaining his degrees of B.S. in 1896 and M.E. in 1905. He was shop foreman of the McKay Metallic Fastening Association from 1896 to 1897, and he was connected with the McKay-Bigelow Heeling Association from 1897 to 1899; production superintendent of the McKay Shoe Machinery Company, 1899 to 1902; mechanical engineer, United Shoe Machinery Company, from 1902 to 1907; engineering editor from 1907 to 1911 and editor in chief of *American Machinist*, from 1911 to 1917; editor, *Industrial Management*, from 1917 to 1920, of *Management Engineer* from 1921 to 1923, and of *Manufacturing Industries* from 1923 to 1928; consulting editor, *Factory and Industrial Management*. He is vice-president of Ronald Press Company. Mr. Alford received the Melville Gold Medal in 1927. He is the patentee of a fixture supporting a device used in reinforced-concrete industrial buildings. Mr. Alford is the author of "Bearings and Their Lubrication," in 1912; "Artillery and Artillery Ammunition," in 1917; "Management's Handbook," in 1924; "Laws of Management," in 1928. He is the vice-president of the American Engineering Council, past-president of the Institute of Management, past vice-president of the A.S.M.E., member of the Society of Industrial Engineers, Society for the Promotion of Engineering Education, National Association of Cost Accountants, American Management Association, Instytut Naukowej Organizacji, Research Committee of the American Engineering Council, which produced reports on "Waste in Industry," in 1921; "Twelve-Hour Shift in Industry," in 1922; "Safety and Production," in 1927; and "Recent Economic Changes," in 1928.

On the whole the ten-year period, 1923–1932, has been marked in the United States by sharp contrasts in results of industrial operation. The mid-point recorded the greatest peak of peacetime activity that industry has ever experienced. As this paper is being written operation is estimated to be only a little more than 50 per cent of normal. There have been three movements of the business cycle in this decade. These are dated as expansion to May, 1923, contraction to July, 1924, expansion to October, 1926, contraction to December, 1927, expansion to September, 1929, contraction to date. Physical volume of industrial production surged up to its highest point in 1929 and then dropped sharply. Commodity prices and manufacturing costs have likewise receded. Statistics of production of the Federal Reserve Board are:

Year	Industrial production combined index, unadjusted
1923	101
1924	95
1925	104
1926	108
1927	106
1928	111
1929	119
1930	96
1931	81
1932 (January through June)	65.6

A comparison of the relation of profits to capital investment for 432 manufacturing concerns gives averages for 1920–1921 and 1929–1931. The figures for the latter period show the decline in profits during the present business recession.

Year	Percentage of profits to capital investment
1920	9.89
1921	1.17
1929	12.82
1930	6.55
1931	2.47

A remarkable increase is shown in the productivity of American industrial wage earners. The percentage rise for all industry from 1899–1919 was 4.7 per cent; that is, productivity had changed but little during the first 20 years of the twentieth century. The change from 1919–1927 is a 53.5 per cent increase. For many industries this change became manifest in the year 1921, thus placing most of the advance in the decade under consideration.

Upon the surge of prosperity that these increases indicate was founded the belief that economic poverty in the United States was almost banished. Some of the more optimistic prophesied that by 1931 or 1932 every one would have an abundance of the necessities of life. In gloomy contrast with this prophecy is the hundreds of millions of dollars already paid out for relief during the past two years and the organization of national relief agencies on a scale never before attempted to mitigate the human misery impending during the winter of 1932–1933.

Unemployment in the United States has fluctuated widely

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

during the past ten years. The estimated minimum number of unemployed among non-agricultural wage and salary earners was at its lowest point in 1923, with an average of 1,532,000. The corresponding estimate as this paper is being written is 11,000,000, with well-founded fears that this number will be increased by 1933. During the first seven years of this decade, employment for industrial executives was quite stable. Shifts in business connection were comparatively few. Beginning with 1930 this situation changed, and the turnover of management personnel has since been rapid.

These circumstances have brought a reversal of belief in regard to American industrial achievement. At about the mid-point of the decade statements like the following were commonly made concerning us: America has made an "immense advance" industrially, "America has experienced a period of unusual industrial prosperity. Millions of people have found their earnings increasing at a more rapid rate than their standard of living." America has become "the first power in the world." As the decade closes this quite different matured judgment of the situation has been publicly declared by engineers: "The problem of the relation of consumption, production, and distribution is one of supreme importance. More and more it will command the attention and devotion of the most intelligent, unselfish, and far-seeing men and women of the body politic. There is no human problem which compares with it in difficulty, in magnitude, in hopefulness. . . . what is being contemplated is nothing less than a purposeful changing of the course of history."

In spite of these violent fluctuations, management has made steady progress during the decade ending in 1932. It has extended to all human activities where work is done. It has contributed to the accelerated rate of industrial development of the first six years, and its principles and practice have withstood the crucial test of the deep depression of the last three. Increasing recognition is being given to the fact that well-managed concerns have come through the period of business recession better than all others. As a function of industrial operation the art of management is now firmly established because of the general acceptance of its fundamentals. The promise of the future is to lead on to a higher professional standing through the development of intellectual, societal, and moral attitudes and values. Should a report like this one be written at the end of the next decade, much of its narration may well be a stirring epic of human achievement.

The nature and extent of the change make the task of reviewing the decadal progress of management difficult. But this difficulty is somewhat relieved by the availability of certain management literature, no prototype of which existed in 1912 nor in 1922. The items which have been most helpful in the study are: "Bibliography of Management Literature," published by The American Society of Mechanical Engineers first in 1927, and revised in 1931; "Progress Reports of the Management Division of The American Society of Mechanical Engineers" from 1925 to date; and parts of the "Report on Recent Economic Changes."

In these contributions two trends in management are definitely pointed out—the one toward increased specialization, the other "more management per man." The "Bibliography" lists in round numbers 800 references (827 by count) covering the 35 years prior to 1923. The comparable figure for 1923–1932 is 5000 items (3915 by count for eight years, 1923–1930). This record indicates an amazing expansion in the volume of management literature. Its character has also changed. Quoting from the foreword of the 1931 edition: " . . . the trend of the development of management [is] indicated by its literature during this period. No longer are there many works dealing with the broad subjects of shop management and scientific management, but rather do they treat of specific phases or branches of management, such as economics, material handling, research, and safety. This, of course, is a logical result of the widespread tendency toward specialization."

Henry S. Dennison, in the chapter on "Management" in "Recent Economic Changes," commenting on the increasing release and utilization of creative and managerial abilities, has this to say: "There is today not only more production per man, more wages per man, and more horsepower per man, but more management per man as well." The reference date is 1928, the mid-point of the decade under consideration.

The approach to this review, as already indicated, is through the emphasized points in the three preceding studies of like nature. From this background the exploration has been broadened to include the activities and developments of management which were found worthy of comments in the annual progress reports. An advantageous difference in treatment between this paper and its predecessor lies in the rather generous introduction of quantitative evaluations. Facts and data of this kind were unavailable in the preceding report years.

Important Findings in Report of 1912:

1 Advance in doing work. "The unquestionable proof of the advance that can be made in unskilled work . . . and in ancient trades . . . . These are the most striking phenomena of all. (Par. 1.)
2 Change in mental attitude. The shift in viewpoint toward production was declared to be "the most important change and one that comprehends the others . . . seeking for exact knowledge and then shaping action on discovered facts." (Par. 22.)
3 Transfer of skill. The application of this principle was emphasized as "the prominent element in present-day industrial management." (Par. 29.) And "we have pointed out that the underlying principle, that is, cause in the widest sense, the application of which has built up modern industry is the transference of skill." (Par. 41.)

Important Findings in Paper of 1919:

The major lines of development in the effort to work out better industrial relations were indicated as:

(a) Profit-sharing plans
(b) Methods of wage payment
(c) Methods and laws to reduce the hazards in industry and mitigate the effects of injurious and occupational diseases
(d) Employment management
(e) Systems of mutual or joint control by employers and employees. (Par. 18.)

Important Findings in Paper of 1922:

1 Management principles. "Acceptance of the principles of management has broadened among engineers, executives in industry, and educators." (Par. 10.)
2 Management methods. " . . . demand for . . . facts as a basis of judgment has grown insistent in all good management. Appreciation of the possibilities and advantages of standardization, simplification, and elimination of waste has spread rapidly during the past two years. . . . The engineering or scientific method has extended in industrial cost accounting. (Par. 11.)
3 Significant developments. Especially significant developments include broadening the applications of management far beyond original Taylor mechanisms, establishment of management courses in colleges, "appreciation of the importance of the human factor in

industry," and declaration that the "service motive must prevail in industry." (Par. 12.)

4 Economics of industry. "Without doubt if a study of this kind be made ten years hence, the developments in economic knowledge will be found to have been one of the great steps taken in the development of management in industry." (Author's closure.)

No similar group of significant developments and trends is offered from the annual progress reports, for the reason that they deal principally with current evaluations rather than trends, but numerous quotations are included to show points of view and steps of progress.

It is unlikely that any two investigators would pick identical items to present as significant in a decade of progress, nor give, even approximately, the same emphasis to each one, nor the same interpretation to the surrounding facts. In this paper the first situation is made partially impersonal by the choice of the items. Of the 25 that are discussed separately, only one, "National Planning," lacks a reference in the preceding reports of The American Society of Mechanical Engineers. As to the second situation, a free use of quotations and citations tends to broaden the area of opinion and to impersonalize the comments.

From this place on, this paper gives a series of summary word pictures of the circumstances of change and progress of the selected developments of management in action. Each is considered separately, although none is independent. "The art of management today [1928] is in large part the progressive adjustment and integration of conflicting needs, conflicting influences, and conflicting purposes."[2]

National Planning. Management is faced with the greatest challenge of its career in the need and demand for national planning and world planning. This summons to still greater achievement comes from the profound influence of the depression that broke like a storm in 1929. More questioning and searching has ensued, directed at the organization and operation of industry, than at any other similar national institution. H. S. Person[3] presents the issue, clearly outlined like the ascending steps of a vast pyramid: "Stabilization of material factors is not sufficient; human relations must be stabilized. Stabilization of production is not sufficient; merchandising must be stabilized. Stabilization of production and merchandising is not sufficient; general administration must be stabilized. Stabilization of an individual enterprise is not sufficient; all enterprises in the industry must be stabilized. Stabilization of one industry is not sufficient; all industries of a nation must be stabilized. . . . stabilization of national industry alone is not sufficient; international economics must be stabilized. Achievement of any of these ends is a step toward a more balanced and harmonious industrial and social world life; each end is but a means to another and greater end."

International planning as a matter of fact must be dismissed at this moment as a stimulating speculation. National planning for the United States is in quite another situation. The idea has grown directly from the experiences with shop planning and the application of Taylor's theories.

The objective of national planning in its economic aspect is to attain and maintain "in the United States a standard of living that is high, broadly distributed, and free from severe fluctuations;"[4] in its industrial aspect it is to stabilize the operating performance of industrial enterprises; in its national aspect it is to minimize the fluctuations of business and avert disaster.

The principles to apply are the enduring fundamentals of management. Methods and technique must be evolved to satisfy insistent needs. Their prototypes are here in the mechanisms and procedures now applied successfully in hundreds of individual plants and in many coordinated industries.

Numerous plans have already been proposed. In general they vary between these extremes:

1 Those that seek to make industrial and business planning a function of the National Government. A governmental bureau, for example, would tell manufacturers what to make, how much to produce, and at what price to sell

2 Those that seek for voluntary regulation of the operation of industry by industry itself, under some governmental supervision to safeguard the rights and interests of the public.

We may confidently look forward to attempts at national planning during the coming decade. Management will give a good account of itself in this new test.

Service Motive in Industry. Scrutiny of the literature and programs of conventions dealing with management reveals that "profit management" has been a favorite topic of discussion. Industrial executives have, in the main, felt and expressed their responsibility toward their own organizations and their investors, and to a lesser degree toward their customers. Toward their employees there has been little evidence of a sense of managerial accountability. This situation might seem to indicate that the fine idealism of Taylor and Gantt had been lost in the general emphasis on profit making. Taylor had the welfare of his fellowman at heart, and spent much of his life's energy in trying to establish mutually satisfactory relations between employees and employers. Gantt challenged industrial leaders with the statement that the life of the community depends upon the service it gets, and that the community needs service first, regardless of who gets the profits.

The statements of two industrial leaders that now follow show that the motive of service is still recognized, although applications may seem to be few.

Gerard Swope (1925):[5] "The reason for the existence of industrial organizations is not first and primarily for profit, but to furnish the community with something the community desires to have. If an organization furnishes something that the community wants, of good quality and at a fair price, it will always be rewarded for that service by an adequate profit."

Benjamin A. Franklin (1926):[6] "Every industrial executive and every owner in an industrial enterprise, whether in whole or in part, strives for and desires a profit. This is the essential reason for ownership. But ownership is no longer, if it ever was, a warrant for profit, for profit must come from the public and from nowhere else. The public is only willing to pay a profit for service, and, with the wider spread of industry, for the best service; therefore, essentially and fundamentally, industry is a service."

No facts can be presented to show how far the ideal of essential service is shaping industrial policy. But the feeling of responsibility toward employees is manifesting itself in operating procedures. The unemployment payment plan of the General Electric Company (1930) and the Unemployment Allowance Act of the State of Wisconsin (1932) recognize such responsibility. Numerous bills to set up unemployment insurance may be expected to be introduced at the 1933 sessions of state legislatures. It will be surprising if some do not become law. The sense of

[6] "The Industrial Executive," p. 100.

responsibility of industrial executives toward their workers seems to be increasing.

Change in Mental Attitude: Adoption of Scientific Method. The change in mental attitude which was noted 20 years ago is still going on. It is a shift to the scientific method. The adopted viewpoint is one that seeks for exact knowledge, and shapes action upon discovered facts. As a doctrine of management it has had great prominence during the past decade. But no one has presented it more forcefully than Gantt: "We have no right morally to decide as a matter of opinion that which can be determined as a matter of fact."[7]

This doctrine has had an influence in developing management procedures. Examples are forecasting, budget planning, and standard cost systems. Management reports, the result of studies and investigations, have been numerously produced, both by organizations and individuals. A few indicate their nature. A complete list of such studies is beyond the scope of this paper.

Economics in Industry. Studies of economic problems in industry with the purpose of resolving into mathematical formulas relations formerly expressed qualitatively in words have made substantial progress. The efforts have been directed principally toward the establishment of rates and optimum levels. The mathematical expressions derived are simple in themselves, but because of the large number of variables involved, and unstandardized economic and accounting practices, which provide many of the numerical quantities, the symbolization adopted has been complex. Simpler expressions must follow before general application of these economic formulas will be possible in industrial practice. Generous appreciation is due to those who have pioneered in this field, and who are thereby assisting in laying the foundation for a new economics. In this group those listed in the adjoining column deserve mention, most of them members of this Society.

Investigators	Economic problems studied
Kimball	Minimum cost point
Davis, Lehoczky, Pennington, Raymond	Economic manufacturing lot sizes
Coes, Hagemann, Kurtz, Norton, Raymond, Shepard, Vorlander	Economic life of equipment
Roe	Economics of small tools
Davis	Economic purchase quantities
Shewhart	Economic control of quality of manufactured product
Knoeppel, Rautenstrauch	Break-even point

Management Principles. Continuing attention has been given to the fundamentals of management. Two codifications of principles and laws have appeared during the past decade. These contributions have important differences when compared with their predecessors. They recognize a comparatively large body of fundamentals rather than a few; they have been stated to connect cause and effect. Three principles have had their first formulation during this period: the Law of Simultation, by Blanchard; the Law of Motion-Time, by Segur; the Law of Operating Rates, by Alford and Hannum. None of these principles as now formulated nor the codes into which they have been combined can be considered as final. Statements of fundamentals need to be brought under review and revision at recurring intervals to keep them abreast of the advances in theory and practice.

Advance in Doing Work: Transfer of Skill. The most striking single industrial advancement in this decade is the increase in the productivity of the individual industrial worker. From 1919 to 1927 this increase, as represented in the physical volume of product, was about 50 per cent. The corresponding increase in utilization of primary horsepower per worker was some 30 per cent. A recent study made by Hannum and the author indicates that in well-managed concerns the increase in the productivity of the worker is continuous, is not affected by business depressions, and is of the order of 4 per cent per annum. These increases are evidence of the expanding mechanization of industry, the widening use of machines and tools, and the extension of the application of the principle of transfer of skill.

The number of references in the Bibliography to Production and Production Control is 16 times more for the decade 1923–1932 than for the 35 years preceding 1923. The comparative figures are 52 to 875; in the latter figure the totals for 1931 and 1932 are extrapolated. This bursting increase in the literature on how to do work suggests the advancement in productivity—namely, the further application of science to the work of manufacturing. Wesley C. Mitchell[8] in answering the question, "What is the prime factor in prosperity?" says: "Since 1921 Americans have applied intelligence to the day's work more effectively than ever before. . . . The old process of putting science into industry has been followed more intensively than before; . . . ."

The Human Factor in Industry: Employment Management. Taking the recurrence of the items in the Bibliography as an indication of interest and importance, labor and personnel matters, the human factor in industry, rank with production and production control. The number of items for the decade 1923–1932 is 871. No one has more succinctly presented the development of man management in industry than Henry S. Dennison.[9] At first " . . . men were called to personnel management who were new to the problem; . . . . Their experience was academic but their outlook was fresh, their sympathies and earnestness were high, many of them had keen and well-trained minds, and they knew enough to begin at once to learn from each other by

[7] "Industrial Leadership," pp. 88–89.

[8] "Recent Economic Changes," vol. 2, p. 862.

[9] Ibid., p. 518.

pooling their experiences. They overcentralized and overelaborated the job, as is always likely at the installation of a new functional department; and in this case all the more so because of the intense pressures.

"With the business stagnation and glutted labor market of 1921, they were virtually swept away, but they left behind them new practices, and old ones modified, psychological and trade tests, job analyses and classifications, rating scales, systematic training, and shop committees. What is of more importance is that they left a habit in the business mind of considering personnel management as a difficult, distinct, and major function of business management. Previously such little selection, training, health and safety work, insurance and social contacts, and joint relationships as had been attempted, had often been administered with no coordination, . . . seldom as serious projects of human engineering."

The process of sweeping away personnel activities, which was so widespread during the depression of 1920–1921, has recurred during the present business recession but in a mitigated form. The situation indicated by the Progress Report of 1931 has not materially changed down to the present time.

"Modern labor management as a whole has by no means been abandoned. Most companies have maintained their industrial-relations programs, and some have even extended and liberalized their labor policies. Unemployment of personnel directors and their associates has probably not been greater than that of other supervisory and staff employees.

"This situation, which is strikingly different from that which characterized the depression of 1921, is to be accounted for largely by the growing usefulness of modern labor management, and by the increased recognition of its usefulness by the leaders of industrial enterprises.

"This gain in usefulness has been due in part to the gradual acceptance of the theory that personnel management is properly a staff or advisory function in the industrial organization, and in part to the rising professional status of industrial-relations directors."

Management Methods: Organization. Three developments in organization have commanded the attention of industrial executives and management engineers: the operating structure itself, the functionalization of duties and specialization of the personnel, the measurement of operating performance.

The depression of 1921 with its disturbance of business relationships gave a new importance to the internal structure of industry and business. Examinations of the principles of organization and the mechanisms whereby they are made effective and are coordinated have been made afresh. One result is the placing of more reliance upon the personnel of an organization, and less upon the static design of that organization as indicated by the regulation organization chart.

Functionalization of types of activity has spread and with it the specialization of individuals. Managers have recognized that to take full advantage of the national aptitudes and exceptional abilities of executives, problems and duties must be narrowed in scope and submitted to special consideration and action. Apart from the Taylor installations, the most significant applications of functionalization have been made during the decade just ending.

Once the structure of an organization has been perfected there arises the need for measuring its operating performance. Numerous studies, but little real progress, have been made in this field. An extensive, though uncoordinated, group of ratios, turnovers, rates, efficiencies, engineering and experiential factors has grown up, the work of many investigators. It is reasonable to expect that a satisfactory mechanism of measurement must be a part of a system of control.

Shewhart,[10] in establishing a mathematical basis for quality control by random sampling, has shown the application of scientific theories to the solution of every-day management problems. But he has done more. He implies that for every function of management, standards of performance can be established in accordance with the normal distribution of each characteristic of the function when influenced solely by a constant system of chance causes.

Three widely used mechanisms of control employ standards as an integral element in their procedure. The Gantt chart plots requirement against actual performance for the same interval of time, a day, week, or month; budgets estimate expenditures for a year, for example, and divide the amounts into weekly or monthly subdivisions; standard costs compare the actual costs with a predetermined standard. In each of these mechanisms means are provided to set a standard performance, to compare the actual performance against it at specified intervals, and to analyze the causes of failures and variations.

The most recently devised mechanism of this nature is based on a somewhat different theory. It is the system of kmh-rates of Hannum and the author, and is based on the principle of operating rates which is stated as: Operating performance is controlled most directly through control of the rates of expenditure of labor, materials, and expense.

In the comparison and harmonizing of actual performance with present standards, or in the control of the rates of input of production factors in industrial operation, may lie a means for the direct measurement of management.

Management Methods: Cost Accounting. The most significant development in management procedure that has taken place during the past decade is in cost accounting. The major credit for this progress is due the National Association of Cost Accountants and that organization's able leaders. This society was founded at the end of 1919, thus the major part of its work is included in the decade under review. Three of its contributions are particularly noteworthy:

1 Raising the status of cost accounting
2 Promoting the use of budgets and developing budgetary procedure
3 Extending the use of standard costs.

Budgets made extraordinary progress following the publication in 1922 of "Budgetary Control" by J. O. McKinsey. No other mechanism of management of similar scope and complexity has ever been introduced so rapidly. A 1931 publication of the National Industrial Conference Board analyzes 162 budget systems. It is estimated that 80 per cent of the budgets installed in industry have been put in since 1922. The depression years 1930–1932 have created situations which have made budgeting difficult in many instances, and have shown the necessity of introducing adjustable means to make the estimates correspond with the possibilities of changing conditions. It is likely that the budget as a master plan will emerge from these troubled years a more useful and effective management mechanism.

Standard cost procedure is second only to budgeting in its growth in cost-accounting practice. Although the first presentation of its methods by G. Charter Harrison was made in 1918, the literature of the art and extension of the methods have come principally since 1922. Standard costs have now been applied in nearly every kind of industry, both intermittent and continuous. The concept behind the development is scientific, the prediction in advance of what the cost of product is to be.

Management Methods: Waste Elimination. Three developments in the economy of industrial operation which have had a rise to a position of prime importance since 1923 are: the elimina-

[10] "Economic Control of Quality of Manufactured Product."

tion of waste in industry, simplification of manufactured products, and engineering standardization. The "Waste in Industry" report of the American Engineering Council was issued in 1921. From the impetus given by its presentation and recommendations have come the movements for waste elimination and simplification. In engineering-society circles no other management topic has received more attention, been the subject of more meetings, and the object of more special effort than that of waste elimination. The concept of preventing or avoiding wastage, a distinct contribution to national economy, has been accepted far beyond engineering and management circles, and has become a part of the directive thinking of many non-technical individuals and groups. President Hoover, when Secretary of Commerce, said of the Waste in Industry report, that if the American Engineering Council produced only one such engineering economic document in fifty years, the existence of the organization would be justified.

Simplified-practice recommendations have eliminated unnecessary variety in sizes, dimensions, models, and types of over 130 commodities. About 20 new projects are constantly before the Bureau of Simplified Practice, which is the coordinating agency for the developments and promulgation of the recommendations.

Some elimination-of-waste surveys in manufacturing plants have indicated a possible saving of $50 per employee per annum.[11] " . . . the savings of American manufacturers from simplified practice and the application of the recommendations of the report on Waste in Industry [is estimated] as upward of $600,000,000 annually." On the basis of this estimate the total saving for the decade 1923–1932 is of the order of five billion dollars.

Standardization while well established before 1923 has made substantial progress since that date. The work has been participated in by individual plants, trade associations, technical societies, and governmental agencies. The movement to create "American Standards" was initiated by a group of technical societies which founded the American Engineering Standards Committee. In 1928 this committee was reorganized to include a broader industrial scope, and the name changed to the American Standards Association. It is now a federation of some 40 national technical societies, trade associations, and Federal Government departments, with numerous affiliations abroad. Up to January 1, 1931, it had approved 181 American Standards, of which only 10 antedate 1923. The economic advantage of standardization cannot be evaluated. The automobile industry claims a saving of $750,000,000 per year. A survey made in 1926 showed that 91 trade associations and technical societies were expending $2,600,000 annually on standardization activities. At the same time the yearly expenditure of the Federal Government was $4,250,500.

Management Methods: Wage-Payment and Profit-Sharing Plans. Financial-incentive wage-payment plans have made steady progress in the extent of application. C. W. Lytle gives a comparison of the distribution of such incentives and day work for industrial workers: "A rough idea of progress can be gained by comparing data from the Gemmill[12] survey of 1922 with those from the Jucius[13] survey of 1932. The former was from representative plants in and east of Chicago, while the latter was from representative plants in Chicago. Both surveys include all sizes of plants and all types of product. Despite differences in scale and location, the figures are probably representative of the progress in the better-managed plants during the last decade." The comparisons are:

	Number of employees		Per cent of whole	
	1922	1932	1922	1932
On time wages	15,630	44,674	53.5	29.4
On financial incentives	13,600	107,489	46.5	70.6

The invention of wage-payment plans has continued. A listing of 1924 recorded 17; a similar compilation of 1932 showed 32. It is becoming more generally recognized that many of these are but variations of more basic plans that are well known.

Five of the annual Progress Reports of the Management Division comment on incentives. From them excerpts have been selected to show progressive changes.

1926: "There has been a revival of interest in this subject. . . . Group bonus has become common, especially in the automobile industry. . . . The prejudice which formerly existed against piece work has lessened as such rates have become guaranteed and employees are learning that piece rate gives them *all* of the wages saved from decreased time."

1927: "Interest in incentives seems to be gaining . . . The cutting of piece rates or commission rates has become uncommon, and the response to such incentives is therefore more wholehearted than ever before."

1929: "For some time a tendency has been developing to make more and more group applications of incentive plans. This is a natural accompaniment of mass production in that more and more work is interdependent. As in all new things, there is, however, a danger of this change swinging too far. Since task standards need only be set for the whole assembly and the subordinate parts merely balanced, it is an easy way to avoid some of the preliminary job standardization and much of the paper work of operating. If equal results were possible, there could be no objection, but it is well established that group effort is neither that of the least efficient nor that of the most efficient, but a mean between."

1930: "There has been a revival of interest in financial incentives. This is undoubtedly due to the fact that the high-wage principle has come to the front, and also somewhat to the mature stage which job standardization has now attained."

1931: "Incentives have continued to spread into lines of work formerly considered too difficult of job standardization."

Incentives for executives, fostered by prosperity, were freely introduced up to 1929, and as freely dropped after the beginning of business depression. The Progress Report of 1929 makes this comment: "Here the incentive is coming from two directions; first, from profits in the form of a fund and distributed according to the estimated contribution of each executive; second, from measurable achievements such as departmental standards of quantity, quality, delivery, and the all-inclusive costs. . . . the type of incentive based on measured results is infinitely superior for all minor executives, and usually so up to the general manager."

Profit-sharing plans have had a negligible record during the decade under review. There is no reference to them either in the Report on Recent Economic Changes or in the annual Progress Reports.

Management Methods: Job Standardization. The high wages that prevailed during the first seven years of the decade just closing stimulated the study of operations and jobs with the purpose of reducing labor costs. Much consulting work has been done in this field. The controversy over the relative merits and possibilities of time study and motion study, which was alive in 1923, has subsided. The harmonizing of these methods of job standardization by Roe and Lytle in "Management's Handbook" has been an important influence in bringing about the change of attitude. In addition to the extension of the utilization of time and motion study, important developments are improvements in the technique and devices for time and motion study, and in motion-time analysis. Segur has based the technique of the latter on the principle of motion time.

[13] M. J. Jucius, "The Use of Wage Incentives," *Journal of Business*, University of Chicago, January, 1932.

Three of the annual Progress Reports contain these comments:

1928: "There has been a pronounced tendency toward a better understanding of time study."

1930: "The application of time and motion study is now spreading in the textile industry, especially in the South. . . . Some of the most progressive labor organizations have begun to insist upon the establishment of standards in their operations."

1931: "There is definitely a revival of interest in the micromotion method of job standardization. This has arisen from the General Electric Company's practice of using the full micromotion method to train its analysts, and of allowing the work of the analysts to be done without the full use of the method. . . . when analysts are trained by the full micromotion method they are so familiar with the principles of correct motions that they are able to make drastic improvements without taking elaborate measurements of existing work methods."

The Society of Industrial Engineers has completed a survey of time-study devices and methods, but the report has not been published.

Management Methods: Inventory Control. Inventory control has been refined and made more effective during the decade of this paper. Concentration upon methods for its accomplishment was stimulated by the shortage of materials during the World War and the excess of stocks during the depression of 1921. Control is sought to hold quantities within prescribed limits, to reduce the risks of damage and obsolescence, and to save the wastes of handling. "One of the dramatic developments . . . is to be found in some automobile plants, where the average inventory has actually decreased from several months' to a three or four days' supply. . . . materials . . . are planned to be taken directly from the freight cars and placed in the manufacturing departments where they are to be used, thus eliminating handling and the expense of stores control."[14]

Management Methods: Materials Handling. An indication of the creative energy directed toward better handling of materials is given by the number of references in the Bibliography before and after 1923. The record is: before, 8; after (1923–1932 adjusted) 251. Improvement has been in the economics and control of handling, in the equipment available, and in organization of material-handling departments. Economies in many instances have been substantial. Thirty-seven installations reported in 1928 had aggregate annual savings of over $850,000. Under this general head is the extension of assembly equipment to allow "straight line" production. Numerous installations in many different kinds of industry show the wide possibilities of applying this principle.

Management Methods: Accident Prevention. The seriousness of the industrial-accident problem began to be appreciated in the United States some 12 years prior to 1923. Workmen's compensation laws were passed, the safety movement initiated, and thousands of persons began to give their attention to ways and means to reduce accidents. The effect of this work was significant. The prevailing number of accidents was cut in half, or to a third, in many industrial establishments. But following the revival of business in 1923 an alarming situation became evident, brought about by the increasing frequency and severity of compensatable accidents and mounting accident costs. The real situation was at first masked by the great increases in production and productivity. While there had been an increase in the hazard of industry per man-hour, production had increased so much more that the hazard in terms of production had decreased.

Following 1923, therefore, the accident problem became this: Can accidents be controlled under modern industrial conditions of high productivity? The National Bureau of Casualty and Surety Underwriters asked the American Engineering Council to investigate this matter. The report of 1928 on Safety and Production presented the results of the study. In brief the findings are:

1 Industrial accidents can be controlled under modern conditions of highly efficient production
2 Safety and production are shown to have a coefficient of correlation of 0.835; "a 'safe' factory is eleven times more likely to be 'productive' than an 'unsafe' factory"
3 Major industrial executives have as much responsibility to initiate accident prevention as to initiate improvement in productivity.

The situation has changed but little since the issuance of this report. The industrial-accident problem is still of major importance. But the attitude toward the question has improved, and the means for its progressive solution are more clearly defined.

Management Methods: Works Councils. Employee-representation plans, or works councils, spread rapidly after the recovery of business following 1922. By 1923 some 700,000 workers were included in these plans. By 1928 this number had doubled. In the management survey of 1928 for the Report on Recent Economic Changes, 20 per cent of the plants studied had active, formal employee-representation plans, 10 per cent dealt occasionally with especially elected employee committees, and 6 per cent were working under union agreements. One of the consequences of the rise of these plans has been the retarding of the growth of organized labor. What the effect of the present depression will be ultimately on works councils cannot be foreseen. It may not be so far reaching as that experienced in 1921–1922. "The year 1921 saw the discontinuance of many arrangements for joint relations, both union agreements and independent employee-representation plans. The serious unemployment at that time and the weakened position of the unions resulted in the abrogation of many arrangements made during the war and boom years. Many plants closed, and when they reopened the employee committees which had previously existed were not revived."[15]

Wage Levels. No other theory of management has ever had such a meteoric rise of acceptance and seemingly an equally meteoric drop in favor as the doctrine of high wages. The theory that high wages accompany high production was practically unknown in 1921, although it had been suggested by a few management engineers. In that year "more than 300 articles appeared telling of methods used in cutting wages and speculating on how far they would fall. By 1922 articles of this sort had disappeared and those about wage incentives had taken their place."[16] By 1926 the doctrine was well established and had been accepted by many able business executives and trade-union leaders. The high wages of these years down to 1930 were an impelling force in the management progress that this paper records. As the depression of 1929 began to be felt, the high-wage doctrine was invoked to maintain wage rates, with considerable success through 1930. The Progress Report of that year states: "The principle of high wages is standing the test of the depression better than many expected. . . . Relatively few of the leading large companies have cut wages per piece or per hour. . . . The very fact that so many leaders are deliberately trying not to cut wages is enough to vindicate the statement that the high-wage theory has come to stay in this country." However, during 1931 and 1932 wage cuts became common.

A study made by the National Industrial Conference Board of the record of 1718 industrial concerns employing 3,358,666 workers in 1929, and 2,391,009 in 1932, yielded these facts:

[14] "Recent Economic Changes," vol. 2, p. 509.

[15] "Recent Economic Changes," vol. 2, p. 529.

[16] Ibid., p. 529.

Nature of reductions	Per cent of companies
Executive salaries	80.5
Other salaries	81.0
Wage rates	75.4

Extent of reductions	Average reduction in per cent
Executive salaries	20.3
Other salaries	15.9
Wage rates	13.9

In general, salary reductions have preceded wage-rate reductions. In 1930, 212 of the companies reporting reduced salaries; 148 reduced wage rates; about 12 per cent of the reported reductions in salaries and 11 per cent of the reported reductions in wage rates were made during this year. More reductions occurred in 1931. The peak seems to have been reached early in 1932.

The ultimate fate of this doctrine cannot be predicted. It has not been abandoned. It may return to general favor and acceptance with the modified meaning that high wages can be paid only for high productivity. The Progress Report of 1931 gives an excellent summary of opposed points of view: "A veritable storm has raged between the orthodox economists, including many of our bankers, and the progressive manufacturers, including most of the engineers. The former group believes that the sooner wage rates are reduced to the same extent that commodity prices have been reduced, the sooner will be the recovery of industry. The latter group, while conceding that a proportionate reduction in money wages need not affect adversely the economic status of the worker, maintains that the real strength of American business lies not in the maintenance of an even balance between wages and cost of living, a continuing equilibrium from year to year, but in a steady advance toward the higher standards."

Working Hours. In 1926 the Ford Motor Company startled industrial executives by announcing the adoption of a five-day week. The move was a natural result of the higher productivity per machine and per man-hour which had been attained. A report of the National Conference Board published in 1931 showed that 270 establishments employing in the aggregate 216,921 wage earners were operating on a year-round five-day-week schedule at the close of 1928. The annual Progress Report of 1930 carries this item: "While a few companies have lengthened the working day in order to pay the same daily wage, in general hours have been shortened and the five-day week has been given greater trial than ever before. In 48 national and international unions there are 532,894 employees on this basis." Continued agitation for shorter working hours and a flexible working week is active, and the practices have many advocates. "Shorter normal working hours would constitute a permanent spread of unemployment. . . . For instance, it is reasonable to believe that if in an industry normally operating 50 hours per week, the working hours were shortened to 40, with 50 per cent overtime pay up to 45 hours, and 100 per cent overtime pay beyond that, the influence of the change would be in the direction of maintaining good business . . . ."[17] The trend toward shorter working hours is one of the most pronounced in industrial management today.

Working Conditions. Increasing attention has been given to working surroundings and conditions during the past decade. Evidence of this fact is offered by the following tabulation of items in the Bibliography:

Item	References before 1923	References 1923–1930
Air conditioning	0	60
Artificial lighting	2	80
Fatigue	7	30
Fire prevention	0	26
Noise elimination	0	6

Ventilation and air conditioning have been utilized to remove dust and fumes and to control temperature and humidity that working spaces may be more comfortable and better adapted to manufacturing processes. Artificial lighting has tended to use brighter and higher unit intensities and is credited with substantial increases in productivity. The situation in regard to the elimination of fatigue was characterized in the Progress Report of 1926 in these words: "This matter has had more propaganda than research. . . . there has been practically no advance in our knowledge of the nature of fatigue and the part it plays in efficient production." Since that statement was written fatigue has had intensive study with a reversal, or substantial modification, of former common beliefs. Anderson's investigation (1930–1931) was under actual working surroundings and conditions. He shows that with good management fatigue is not a major consideration: "Progressive, modern manufacturing methods and management are rapidly eliminating real fatigue from industry. At the present time satisfactory outputs at low cost may be had without unduly timing workers, and in industrial work can be, and probably will be, of little importance." Fire prevention and protection in industrial plants has kept pace with the improvement in maintenance. Noise elimination is just beginning to receive attention, with as yet no tangible results to record.

Industrial Plants. Two possible tendencies in the locating and planning of industrial plants are worthy of attention, although neither is strongly evident at this time. The first is toward the locating of industries in small centers; the second is toward selecting the small unit as most economical in operating performance. In regard to the one, the American Engineering Council says:[18] "The decentralization of manufacture which is engaging the attention of industrial leaders offers a useful method of striking a balance between agriculture and manufacturing. While a few industries, like the manufacture of steel, must be organized on a scale so large as to surround themselves inevitably with urban conditions, this is not true of the greater number. They can properly be divided into smaller units. The present tendency is to locate units in smaller communities in closer contact with rural conditions." In regard to the other, recent studies strongly indicate that the optimum size of plant for effective operating performance is much smaller than is commonly believed. On the operating side, plant maintenance has assumed new importance because of its influence to increase production when bad-order machines are avoided and its effect in arresting depreciation.

Obsolescence of Equipment. Management has begun to deal with the obsolescence of equipment from two points of view. The one is that far too much machinery and other physical property is in use, or held for use, which actually is obsolete and should be disposed of. The other is that, due to the depression, actual values of previously acquired plants are lowered and assets should be written down accordingly. Two comments appear in the annual Progress Reports:

1928: "The replacement of obsolete equipment is considered to be one of the principal factors in good management."

1929: "Probably the most important questions that confront the manufacturer today are the relation between the condition of equipment and profits and the replacement of machinery which in point of service may have many years of usefulness but which is incapable of satisfying the latest fancies of the consumer market or competing with more recent and improved machinery. . . . Experience is showing in these competitive days the mathematical relation between obsolete machinery and profits is an inverse ratio. . . . The important phases of the industrial-equipment studies are: (1) to bring out facts showing the relation of equipment obsolescence to production costs, and (2) to dis-

[17] Progress Report of Committee on the Relation of Consumption, Production, and Distribution of the American Engineering Council.

[18] Progress Report of Committee on the Relation of Consumption, Production, and Distribution.

cover, if possible, a means for correctly evaluating and providing for obsolescence in cost accounting."

Industrial Research. Industrial research has as fully demonstrated its value during the months of business depression as any other management function. In spite of bad conditions, expenditures for research in well-managed plants increased in 1931 over 1929, laboratory efficiency has improved, and research has aided in these definite ways: by reducing costs, improving products, developing new products, increasing customers' goodwill, and in some instances is credited largely with the earning of profits.

The demands of the war gave a great impetus to research through the physical sciences. A report of the National Research Council of 1920 lists 300 organizations for research. Included are company, joint, consulting, commercial, trade association, and university laboratories. A further report in 1927 lists 999. Rough estimates of expenditures for basic production research as of 1928 ranged upward to $200,000,000 annually. Since 1921 business procedures and economic forces have been added to chemical and physical research. Numerous references in this paper are evidence of the work already done in these newer fields. Methods for statistical research and market analysis are examples.

An assay made by the National Research Council in 1928 gave the major emphasis on items of industrial-research programs in this order of frequency:

1 Improved product or service
2 Reduction of production costs
3 Development of new fields of application
4 By-products and new materials
5 New products.

A similar, though less extensive, assay in 1932 gives indication of the effect of the depression.

Expenditures for research in percentage of establishments, comparing 1931 with 1929:

Increased	75
No change	15
Decreased	10

Laboratory efficiency, comparing 1931 with 1929, expressed in percentage:

Increased	87
No change	10
Decreased	3

Emphasis in research programs in 1931 expressed as percentage of frequency of appearance:

New products	38
Improved quality	37
Reduction in production costs	19
Development of new fields of application	5
By-products	1

Industrial-Engineering Courses. The major change in industrial-engineering courses of engineering grade has been the increase in number and in enrolments. The number of institutions giving this work has increased from 10 in 1922 to 35 in 1932. The number of graduates in 1922 was 311, and the number of graduates in 1931 from 30 institutions was 596.

In 1923 the Society for the Promotion of Engineering Education undertook a comprehensive study directed to the improvement of engineering education. The investigation was completed in 1929. In the fact-finding stage of this study engineering-college graduates were asked what subjects they regretted missing in college. Seven of these and the number of men mentioning them follow:

Business administration	456
Economics	226
Accounting	179
Psychology	122
Salesmanship and advertising	118
Industrial management	104
Production and production methods	33

This record is an indication that graduate engineers feel the need of courses such as are included in industrial-engineering curricula. An indication that engineering educators are alive to the situation is found in the fact that industrial-management subjects occupied a prominent place on the program of the summer schools for engineering professors, held under the auspices of the Society for the Promotion of Engineering Education at Purdue University in 1930 and at Stevens Institute of Technology in 1932.

Lytle[19] has summed up the major purposes of industrial-engineering courses as:

1 To formulate the principles of an emerging profession
2 To prepare more adequately many men who are to enter this profession.

The situation seems favorable for major advances in the teaching of industrial engineering in the years immediately to come.

Marketing. Among the new problems that assumed importance during the decade 1923–1932, none has led on to more discussion than management of marketing. One-fourth of the section on management in the Report on Recent Economic Changes is devoted to this topic. In the Bibliography there are seven items on sales management up to 1923. From 1923 through 1930 the total is 181. Marketing is commented on in each of the annual Progress Reports beginning with 1926. The Taylor Society has been the leader in developing the science of marketing and in applying scientific-management principles to selling. The American Management Association has a division devoted to distribution problems and has made marketing practice a major topic in its programs. However, the progress made must be judged as slight. Marketing technique is crude both in its planning and execution. A few tendencies have asserted themselves: functionalization of selling activities similar to that which has taken place in manufacturing; adoption of the sales budget; accounting for sales expenditures; scientific pricing of product; analysis of markets; setting sales quotas.

The year-to-year comments in the Progress Reports show something of the developments of the attack on the problems involved:

1926: ". . . these principles [of management] are extending beyond the old engineering type of industries and are becoming popular in industries less accustomed to engineering methods. Offices and retail stores are resorting to them. . . ."

1927: "The trend is toward intensive rather than extensive marketing. . . . Part of the advertising budget is being taken for research to ascertain what the consumer really wants."

1928: "There is a growing interest in the cost of marketing, and more specifically in the cost of marketing activities."

1929: "Relatively little progress has yet been made in analyzing distribution costs from the standpoint of the cost of handling individual items or performing individual services. . . . Investigations in wholesale and retail distribution for several lines of trade, with particular reference to the small as well as the

[19] "Collegiate Courses for Management," International Management Congress, Amsterdam, 1932, and *Engineering Education*, (S.P.E.E.), vol. 39.

larger producer and also to the several methods of distribution, show the possibilities for reducing costs through more uniform methods."

1930: "Experiments in distribution have continued and some progress has perhaps been made, but it has not been sufficient to allow much specific discussion. . . . There has been increased appreciation of the fact that as a rule it is necessary to market those commodities which the consumer wants or can readily be brought to want . . . industry is coming to realize that its raw materials are the needs and wants of persons."

1931: "The field of marketing is now in the greatest need of sound common sense and engineering skill. . . . The demand for useful products cannot be forced into being. . . . It has been recently recognized, both in private investigations and by governmental analysis, that it is very nearly universal in industry today to find that approximately 80 per cent of the volume of production exists on approximately 20 per cent of the number of products in the line. . . ."

Association and Society Activities. The open-minded interchange of trade and technical information has been a factor of importance in the progress of the immediate past, and promises to occupy an even more important position in the business practice of the future. "What is raising the whole standard of management in the United States is the habit among employers of discussing their problems openly among themselves, of comparing the methods of one industry with those of another, and of founding associations for research and conference. . . . They are not afraid to teach each other, nor too proud to learn from each other."[20]

In 1926 the Department of Commerce listed nearly 9000 business associations; in 1928 the number was 13,000; by 1930 there were 19,000. Some are local in scope, others state-wide or interstate, still others national or international. Their activities range "over almost the whole field of management, including especially statistical service, cost accounting, industrial and commercial research, simplification, standardization, credit information, traffic and transportation studies, and trade ethics. It is significant that several hundred business executives are members of some national association of the social sciences."[21]

The membership in management societies has likewise increased during the past decade, the influence of the organizations has widened and strengthened, and the reports and papers sponsored by them have greatly enriched management literature. Among themselves the societies have entered into close cooperation and have participated in numerous joint activities. Management Week meetings in the United States and Management Congresses abroad are examples. Management Week was instituted in 1922 to promote interest in the function of management and to further disseminate information on its principles and practice. During the week designated in 1926 meetings were held in over 200 cities. From that high point interest waned until the plan for a week of organized activities was abandoned in 1929. Five International Management Congresses held in Europe have been participated in through the American committee representing jointly The American Society of Mechanical Engineers, the Society of Industrial Engineers, the American Management Association, the Taylor Society, and the National Association of Cost Accountants. The meetings were held in Prague (1924), Brussels, Rome, Paris, and Amsterdam (1932). Fourteen papers were contributed to the Amsterdam meeting. In addition there were several American papers presented at the Management Session of the World Engineering Congress held in Tokyo in 1930. Still further, American support has been active in the establishment and maintenance of the International Management Institute, with headquarters in Geneva. These contacts in foreign countries have served to show, with new emphasis, that management is universal.

Discussion

WALLACE CLARK.[22] The Alford progress reports are of great value, not only as authoritative records of the history and practice of management, but as a source of inspiration to engineers and all others working in that field. The writer is impressed by the breadth of this report and by the certainty it gives that the influence of management on human life is greater than ever before and more widely understood.

It is good to hear that the service idea in industry has survived the grave difficulties of the last few years. All honor should be given to those companies that have made efforts to keep their workers and to spread their work. The most encouraging statement is that some real progress is being made toward national planning, for this seems to be the best protection against the recurrence of another serious depression. Even then, our national planning must be coordinated with that of other countries or it cannot be wholly effective.

DEXTER S. KIMBALL.[23] Mr. Alford again has presented in concise and clear form the progress of industrial management, and this paper is a most welcome addition to those that he has already written marking the progress of industry. The paper is well documented, indicating that as usual what has been written bears the marks of scholarly research and is not merely a passing opinion. Several of his findings are of more than usual interest.

First, he calls attention to the changed viewpoint of all manner of people at the close of this decade as concerns the ultimate good of the vast industrial machine we engineers have built up. Dismay and doubt have succeeded admiration and applause. The problem of distribution has transcended that of production, and as the author points out, this in itself challenges the engineer and the industrialist to so direct management that it will "lead on to a higher professional standing through the development of intellectual, social, and moral attitudes and values." The point is well taken and should command the attention of every engineer and industrial leader.

The next important impression gained from the paper is his findings to the effect that in spite of this industrial debacle the principles and practices of scientific management, so called, appear to be firmly established and have apparently suffered no loss of prestige. He notes rather that progress along these lines has been constant even during the last few years, and he concludes that "the change in mental attitude which was noted 20 years ago is still going on. It is a shift to the scientific method."

This is highly important when one considers the new ideas of industrial planning which he discusses and which have appeared for the first time in our literature during the past year. Mr. Alford notes quite correctly that industrial planning in an effort to make production and distribution balance is a natural outgrowth of Taylor's ideas of shop planning which are now so familiar to all industrialists. He quite properly dismisses international stabilization through planning as out of the question at present, but the writer agrees with him that we shall, in the next decade, hear much about industrial balance or stabilization through national or private planning or both. This is perhaps

[22] Consulting Management Engineer, New York, N. Y. Mem. A.S.M.E.

[23] Dean of Engineering, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

the greatest and the most difficult problem that confronts us.

Mr. Alford also brings to attention as a problem of management the theories of wages which are now so much discussed. Here we touch upon difficult economic theory which we as engineers are not as yet in a position to debate with much success. Yet this and the correlated question of the length of the working day are matters with which the engineer in general and the industrial engineer in particular must concern themselves, for no doubt they are intimately connected with industrial recovery and stabilization.

ROBERT T. KENT.[24] The author has undertaken a task of no mean order when he attempts to evaluate the progress of management during a period that presents such contrasts in management problems as does the decade under review. That he has been able to trace real progress, notwithstanding the chaotic conditions that have tried the souls of management during the past three years, is a tribute not only to the author's power of analysis, but also to the soundness of the basic principles of management itself. The method that the author has adopted is unique. Nevertheless, it is probably sound, for the literature of a great movement undeniably reflects the thoughts of those who are participating in that movement. The facts and data are exhibited in the paper. The interpretation of these facts and the conclusions drawn therefrom are the author's own. It is with these interpretations and conclusions that others may disagree.

The writer does not wish to take the position of disagreeing. On the contrary, he agrees with most of the statements made by the author. He believes, however, that more stress could well have been laid upon certain points, and it is these points that the writer desires to discuss.

Under the head, "Advance in Doing Work, Transfer of Skill," the author refers to the increase in productivity of the individual industrial worker, and states that the increases in productivity are evidences of the expanding mechanization of industry, the widening use of machines and tools, etc. It would seem that an opportunity has been missed here to point out the necessity of the education of the people, as a whole, in the fundamental principles of political economy. The author has not only laid open himself, but the entire engineering profession, to the charge that he is giving evidence in support of the economic fallacy of technological unemployment. Every engineer who has studied industry, its history and its future, knows that the mechanization of industry does not permanently decrease employment, but in the long run increases it. At this point, where the author shows that the productivity of the individual worker has been increased by mechanization of industry, he also should show how this mechanization of industry has created more employment for more people in the long run, and that therefore the mechanization of industry still further is a desirable thing. This is true, notwithstanding the outcries of those who oppose the machine age, sometimes from political motives and at other times from pure ignorance.

In his section on "Machine Methods and Organization," the author speaks of the measure of operating performance. A careful reading of this section indicates that he refers more to the measurement of the operating performance of the personnel in the organization than to measurement of the performance of the management as a whole. The writer believes that the late and the present unpleasantness through which we are now passing has revealed as nothing else could do the woeful need that we have for some standard of measuring the effectiveness of management itself. This has been pointed out several times, but apparently no systematic study of this subject has ever been made. Several years ago Prof. J. W. Roe presented a paper before this Society outlining a tentative method for the measurement of management. It was offered as a starting point from which we could begin the development of a system or method or plan for the real measurement of management itself. So far as the writer has been able to discover, and he has made many earnest efforts so to do, no one has ever even attempted to apply the principles enunciated by Professor Roe, and one of the most valuable papers ever presented before this Society is an unused tool of exceptional value in a crisis such as we are now experiencing. The most important thing before management today is to learn how to evaluate itself and its own effectiveness.

Budget control is the subject of a single paragraph in the section on "Management Methods, Cost Accounting." Here again the experience through which we are passing has demonstrated that budgets are far from being the instruments of perfection that they were considered to be during the golden years that ended with 1929. This is not said in derogation of budget control. On the contrary, if it had not been for budget control, our experiences during the last three years would have seemed mild compared to what they would have been had not budget control been as well established as it was. The point is that budgeting has failed us only in the respect that we have not yet learned how to accumulate data which will enable us to make better forecasts—in other words, to make more accurate predictions of income. In a period of falling commodity prices, falling volumes of business, and all the other concomitants of a first-class business depression, those who have been in the management end of industry have seen the most carefully made budgets become worthless within a month of their completion, simply because of inability to forecast the income figures correctly.

Budgeting will not become an exact science until we have learned how to accumulate data and to interpret these data in such a manner as will enable us to forecast income as accurately as we can now forecast expense. The problem is thus simply stated. The solution of it is one of the major jobs ahead of the engineering and management professions.

Wages will always be a subject of controversy. Whether to keep wages high and maintain individual purchasing power or to cut wages and keep more people at work will always afford a theme for discussion between two different schools of economics. The author states that during 1931 and 1932 wage cuts became common. These wage cuts were made in most cases only in desperation, as the last thing that many manufacturers could do to save themselves from bankruptcy. More and more have manufacturers and leaders of industry come to the conclusion that the way to prosperity is to build up the purchasing power of the great body of industrial workers. Hundreds of manufacturers in the past three years have gone deeply into their surplus, and in some cases have wiped out their surplus, before wage cuts were put into effect. The table of percentages of reductions in wages and salaries given by the author is significant in that executive salaries were cut more deeply and in more cases than wages. This table shows very clearly that the executives in charge of industry realized not only their duty to their country, but to their employees as well, and that when punishment was necessary, they took their own punishment first.

Under the head of "Working Hours," the author calls attention to the decrease in the length of the work week or work day. While this has nothing to do with the paper except as a comment upon the last sentence—"that the trend toward shorter working hours is one of the most pronounced in industrial management today"—the writer believes that it is significant that every improvement in mechanization and in management has tended toward the shorter working day and the shorter week. It will be recollected that when the factory system first started, the 14-hour work day was common in England. The writer remembers,

[24] Vice-President and Director of Engineering, Divine Bros. Company, Utica, N. Y. Mem. A.S.M.E.

as a boy, of hearing of certain places where they still worked 12 hours a day, and in the 1890's the working week throughout industry was 60 hours. Inasmuch as consuming power can grow but slowly while productive power can be increased rapidly, it is only logical to assume that the remedy for our so-called overproduction is to produce less; that is, we should follow the trend that has continued since the beginning of the factory system and use the greater productivity to give us more leisure in which to enjoy the increased earnings that better machines and better management will give us. The writer believes that the five-day week is inevitable within the next few years. It would not surprise him to see the four-and-one-half- or even four-day week become universal within the next quarter century.

The author gives considerable attention to the improvement in working conditions. Working conditions have a direct relation to costs. Improved working conditions have not been brought about particularly by any altruistic spirit on the part of management, but by the realization that with better working conditions, increased production and consequently lower costs are possible. In this same section is mentioned the reversal of ideas concerning fatigue. Arguments pro and con in regard to fatigue are rather academic. Fatigue automatically is eliminated by better working conditions and by good management methods. The fundamentals of good management, as stated by Taylor, in which he demonstrated that fatigue is an important element in the determination of the daily task, still hold good. The fact that fatigue does not seen to play so important a part today is simply due to the fact that machines, work places, working conditions, etc., are so arranged that fatigue is not engendered in the way that it was when Taylor wrote his classic.

In discussing the location of industrial plants the author quoted from the American Engineering Council, which says that the decentralization of manufacture is engaging the attention of industrial leaders. One of the things that management will come to in the near future is extensive decentralization of industry. From his experience in plants located in large cities, and also in the largest city in the country, and in plants located in the smaller cities, the writer will unqualifiedly put himself on record that the plant in the small community is far and away better located than the one in the larger community. Not only are there better opportunities for good management, but the workers are more contented and have more of an interest in their employers' business, have more leisure in which to enjoy themselves, and therefore approach their work in a better frame of mind.

Under this same subject, the author discusses the maximum size of the plant. The writer believes that in future the trend will be toward the smaller plant, and more plants in the larger companies. During the war, the writer was closely associated with the management of a plant where were employed 4500 to 5000 men and women in diverse occupations, under a single directing head, the general manager. While this man was one of the ablest of managers, the multifarious duties involved in the management of such a large number of employees was beyond the capacity of any one individual. The writer then formed the theory that in every industry there was a definite upper limit to the size of plant that could be efficiently managed under a single head, and that when a company grew to a size larger than this, the proper procedure would be to subdivide it into two or more plants, each of which would be smaller than the economical management limit of size.

The author outlines in considerable detail the progress that has been made in industrial research. Extended comment on this is unnecessary, except to state that it might have been well to emphasize that research is the foundation stone of industry and that there cannot be too much of it.

The author gives some consideration to the subject of industrial engineering education. At the risk of being branded a heretic, the writer will put himself on record that, in his opinion, industrial engineering education is, *per se*, highly overrated. It is a mistake to train young men specifically in this branch of engineering. Engineering students should be grounded thoroughly in the fundamentals of science, in sociology, English, and good common sense. If they have this foundation, they will quickly absorb the principles of industrial engineering as soon as they get out into the world. The engineering educational schools seem to stress too much the mechanisms of management to make good industrial leaders.

The writer finds himself in complete agreement with the author's statements concerning marketing. We have much to learn on the application of the principles of management to marketing. While the fundamental principles of management are applicable to marketing and distribution, just as much as they are applicable to production, the application must be along different lines than those used in the shop. The standards must be different, and the technique must be built up. Nevertheless, if the principles of management as applied to marketing were as thoroughly understood as they are when applied to production, it is probable that much of the distress of the past three years would have been avoided.

In his treatment of association and society activities, the author does not make clear whether or not he includes in this category the trade associations. While some of these are mere price-fixing agencies, others, and the writer believes the majority, are powerful forces for the advancement and stabilization of management. The writer has had experience in several trade associations, and it is his observation that they are the one big factor that will tend to stabilize industry, prevent cut-throat price competition, lead to cooperation in the stabilization of markets, and that they will be the promoters of extensive industrial research that cannot be undertaken by individual companies. The trade association may well become to an industry what the planning or production-control department is to the factory.

CARL L. BAUSCH.[25] Another item should be included as a part of the ten years' progress report and as an essential for recovery. This is unemployment insurance. In February, 1931, the Rochester Chamber of Commerce reported that fourteen companies had adopted the unemployment benefit plan. The plan is as follows:

All employees receiving less than $50 a week are included. The benefit will be 60 per cent of the weekly earnings, with a maximum of $22.50 a week, payable after two weeks of unemployment. The benefit will be paid only to employees laid off on account of slack work.

The fund will be accumulated by the concerns laying aside up to 2 per cent of their pay-rolls for the year 1931 to 1932. No contributions will be made by employees during normal times. If after the plan is started and it seems to the management that the fund is inadequate, an emergency may be declared and a 1 per cent assessment made on salaries of those getting over $50 a week. In such cases the company will contribute an additional equal amount.

All plans looking toward business recovery must include means to bring about a feeling of confidence in the minds of labor as well as of capital.

WALTER N. POLAKOV.[26] There is no reference in the report to the influence of power production in the changing aims and

[25] Manager, Research and Engineering, Bausch & Lomb Optical Company, Rochester, N. Y. Mem. A.S.M.E.

[26] Walter N. Polakov & Co., Inc., New York, N. Y.

methods of factory management. In the machine age and prior to the appearance of machines the object of management was to make the worker personally more efficient. Training of workmen in the habits of industry, time and motion studies, premium systems, and task work with bonus were designed to that end. With the advent of the power age, machines became emancipated from the shackles of belts and gears. Driven by individual electric motors, machines are now easily relocated to suit the sequence of operations, thus upsetting all traditions concerning material handling, partly finished stores, shop dispatching, etc. Electrified machines are now frequently automatically loaded, adjusted, driven, controlled as to dimensions, unloaded, and output recorded, wholly automatically. There is a definite trend toward the "automatic factory" where no human hand touches the product throughout the operations. There are numerous skelp mills, rolling mills, aluminum plants, paper and pulp mills, cigarette factories, etc., where the transfer of skill and transfer of power from worker to machine are so complete that the functions of workers are chiefly supervisory in their nature.

This changes the labor specifications from demanding trade skill and physical force to new requirements of a psychological nature: (1) Sustained attention, (2) correct perception, (3) prompt reaction. These qualifications are becoming essential labor characteristics, since observations of instrument indications in continuous processes demand sustained attention to all such factors as pressure, temperature, humidity, concentration, speed, etc. Then, these instrument indications must be correctly perceived and interpreted, so that prompt action may be taken before any damage is done by the changing conditions. This new role which labor is now increasingly called to play eradicates the old distinction between manual and mental labor, fusing them as the machine itself is fused with a motor and electrical controlling devices. Consequently, the main function of management is the securing of an uninterrupted flow of production. This function is becoming the more important as the first cost of the automatic equipment, and hence the fixed portion of capital charges, is getting not only far greater than it was before, but it generally exceeds many times the pay-roll.

This definite aim of securing an uninterrupted flow of production largely depends upon the managerial function of planning. Within the last decade this problem of planning of production, originally evolved out of the principles laid out by Taylor and perfected by Gantt, is spreading beyond the walls of a shop or a plant and has become a grave problem of planning within an industry, within a nation, and even among the nations. Hence we observe the movement to modify the anti-trust law, to plan and control the production of oil and cotton and other commodities, to plan import-export trade and readjust the tariffs, and even to plan concerning international war debts. The management engineer who a few decades ago was confused with an "efficiency expert" is looked upon today as one peculiarly fitted by his experience in planning to give advice on major economic problems.

L. W. Wallace.[27] The paper has omitted any reference to the conference of the leading industrial and commercial men of the nation held in Washington in December, 1929; that in this conference they committed themselves not to reduce wages if it could possibly be avoided; that this action signified that the fundamental principles of good management have become embedded in the minds of our leaders; and that they recognized the importance of maintaining good personnel relations. As a result of this commitment and the sincerity with which it was followed, American labor realized that management was doing everything it could to safeguard its interests during this depression.

As a result of this, during these strenuous times there have been less labor disturbances than in normal years. This fact is a great credit to both labor and management, and will become historical. It is one of the most significant events in the realm of management during the last ten years.

In a broad sense and over a long period of years, there is no such thing as technological unemployment. Due to technological advance there has been a shift in occupations, all tending to elevate the position of industrial workers. More skill, intelligence, and judgment are required to construct and operate modern equipment than under old methods; hence industrial workers have been greatly relieved of drudgery and are receiving higher compensation.

Lillian M. Gilbreth.[28] In his 1912 report on the progress of management, the author referred to the transference of skill as of great importance, and his writings ever since have shown that he continues to feel this. It is not easy to define skill. The best that we have been able to do is to define it as "knowledge, plus dexterity, plus adaptability." Psychologists and engineers would seem to agree that knowledge and dexterity are necessary for skill; there is as yet little realization of the great importance of adaptability. Yet this is fundamental, for intensive studies of skill show that the man who possesses it can adapt to changing situations, and it is this adaptability that distinguishes the skilled man from any machine that may be invented to take over the work that he does.

If adaptability is accepted as part of the definition of skill, then skill can never be transferred from a man to a machine, though it can be transferred from a man to a man. And we need have no fear that machines will ever make skill unnecessary. Machines may embody knowledge and furnish repetitive dexterity, but cannot adapt themselves to a changing situation, as can a man.

The implications of this are many. Materials, if they are to facilitate machine operation, must be carefully standardized. If they are to conserve and develop skill, it is thinkable that not such close inspection is indicated. Machines should take over drudgery and such repetitive work as requires no adaptability. Men should be assigned to work that will require as high a degree of adaptability as they can supply, if their skill is to be conserved and developed.

In motion study, we are careful always to keep the consideration of maintaining, developing, and using skill a part of the program. The chief emphasis is on developing men, rather than on making things or inventing machines.

As a Society, we have made great progress by adding economics to the subjects discussed at meetings. We could make similar if not greater progress by adding psychology. A study of our programs during the last 20 years shows that we are including the human element more and more in our discussions of management.

But as yet we do not include the principles and practices of psychology, which concerns itself with the developing science of human behavior.

Our great need today is to realize that we can develop the human element along with our machines and our materials. This can be most appropriately done by discussing skill, its definition, its transfer, and its development, and it is to be hoped that every program of the Management Division will contain a place for such discussion.

[27] Executive Secretary, American Engineering Council, Washington, D. C. Mem. A.S.M.E.

[28] Gilbreth, Inc., management engineers, Montclair, N. J. Mem. A.S.M.E.

G. M. EATON.[29] The writer challenges Mr. Wallace's statement that there is really no such thing as technological unemployment. As a statement of long-time average considerations, the writer agrees with Mr. Wallace on the job-creating achievements of technological advance. But we are evading the issue when we deny the more or less transient unemployment attendant on every broad technical advance.

To give one specific illustration, the interests with which the writer is connected laid off nearly 300 skilled men when, along with the rest of the steel industry, they replaced hand labor with machines for the removal of surface defects from steel blooms. Do you think you could convince those 300 men that technological unemployment is imaginary? As they tightened their belts, they would resent defining their hunger period as transient.

We have been told that the engineer must get off from the beaten trail in his economic thought and be guilty of appearing radical. Very well, let us be radical for a moment. We have been told of organized effort to train men of skill, men of knowledge, dexterity, and adaptability, so that they can apply their skill to carving a living in a new way. The writer wishes that it had been brought out that too much of this effort is now necessarily exerted after the emergency demanding the change has arisen.

There was time enough in the interval between the sure knowledge that hand chipping of blooms was a dying art and the commercial availability of the machines to plan the transfer of the men whose art was evaporating. But it was nobody's business to do this, and the job was left to the slow process of evolution.

Our attention has been focused on the uselessness of a budget where only the expenditure side has been forecast with accuracy and little is known about income. When we budget employment in terms of man power and know little about the coming demand for men, our budget falls into the same category. Unemployment can be foreseen in just about the degree that we organize for this advance knowledge.

When the Pennsylvania Railroad foresaw the end of wooden cars, it transferred the skill resident in the workers from wood to steel, and did this ahead of the emergency, so that no men were laid off.

We dare to disclose our epoch-making ideas to the Patent Office for our own gain. Will we ever dare to disclose them in some similar manner to a planning agency for the welfare of others? This is radical; but it is worthy of hard-headed thought.

ERIK OBERG.[30] The paper presents not only a most comprehensive summary of what has taken place in the last ten years in management engineering, but a prophesy of the future as well. The parts relating to industry planning and the service motive in industry are especially important, dealing as they do with the broader aspects of management. We engineers have been so busy delving into the physical laws of engineering that we have almost forgotten the purpose of it all. We have begun to look on the means as an end, and the result has been all too obvious during the past three years.

Management has to do with the running of industry efficiently. Industry is not running efficiently when a large part of its machinery stands idle and millions of workers are idle also. To that extent, management has failed, because it has not been built upon a broad enough basis. It has not had an adequate conception of fundamental economic laws. To acquire such a conception, however, is the business of management.

Most of the investigations into our economic difficulties, it seems, have not been undertaken with the courage that the engineer displays in attacking engineering problems. In engineering, we are not tied to tradition; but when we deal with business or economics, we are too partial to the methods and practices of the past. We fear to examine too critically into established commercial and economic principles. We dare not question old institutions lest we be labeled too radical; and so, in our fear of mere words, we fail to see clearly that which is obvious.

Now management must learn to see a few of these obvious things, if we are to build a rational industrial system for the future. Suppose that for the moment we forget completely the intricacies of our traditional economic methods and examine a few of the obvious facts in the world about us, just as an engineer would examine a mechanical problem. Let us try to formulate a few economic axioms—facts on which management would build, if there were no past practices to be taken into account. It seems to me that a few of these axioms are as follows:

1 We are physically able to produce more food, more clothing, and more housing—that is, more necessities—than the nation is able to consume. In addition, we are able to produce an abundance of comforts and luxuries. Yet, millions who are able and willing to give their full share of useful labor to society suffer for lack of these very necessities, let alone the luxuries.

2 When labor applied to nature produces abundantly of wheat, cotton, or other products, we ought to be prosperous. These bounteous gifts of nature ought to be welcome. Yet, our economic practices are such that ample crops are a menace. Unemployment, hardship, and depressions follow the presence of abundance in the things we all need for health, comfort, and well-being.

3 When men work efficiently, their reward ought to be security and comfort. As it is, efficiency apparently causes overproduction, and to both the engineer and the manual worker, it appears that the more efficiently he works the more insecure is his job.

4 Mechanical means for production that save toil and labor should be a blessing to mankind; they should create more leisure, greater comforts, and greater security. Instead, they appear to create insecurity, unemployment, and suffering.

5 Money is not a commodity like wheat, cotton, or iron ore; it is a means of exchange. Pieces of paper or pieces of metal used as money do not, by themselves, satisfy our needs or add to our comforts. But our economic practices seem to have made of money something more than a means of exchange—something that by its mere "scarcity" or "abundance" may create abnormal and undesirable conditions, irrespective of the scarcity or abundance of the actual commodities that we want and that we make use of.

6 The object of engineering is to obtain the greatest amount of product with the least amount of work; the object of trade is to obtain the greatest amount of goods for the least amount of work given in exchange. Hence it should be advantageous for a nation, as well as for an individual, to obtain an abundance of goods from abroad, in exchange for the minimum amount of labor on its own part. Yet, our economic practices make it undesirable for a nation to obtain goods cheaply—that is, with the expenditure of a small amount of labor—if these goods come from abroad. Under our economic methods, nations believe that they promote their prosperity and well-being by working harder in order to produce greater quantities of goods to send out of the country (exports) than they are to receive in return (imports). Briefly, in international trade, by getting as little as possible in return for our own products, we are supposed to grow prosperous.

7 Property is clearly of two kinds: Property that has been created by the exertion of man, and property that has been created by nature without human effort. Our economic practices

[29] Director of Research, Spang, Chalfant & Co., Inc., Ambridge, Pa. Mem. A.S.M.E.

[30] Editor, *Machinery*, New York, N. Y. Mem. A.S.M.E.

deal with these two kinds of property largely as if there were no distinction between them. There is also a form of value generally termed "the unearned increment" that is not created by individual effort, but by the cooperation of society as a whole. This we label "private property," just the same as the products of man's individual exertion. Many of our economic ills may be due to this confusion of ideas in regard to property.

8 Waste of human labor, due to unemployment, is the most costly waste of our industrial system. If calculated in dollars and cents, during years such as 1931 and 1932, it mounts into figures greater than any other waste for which management is responsible.

It seems to me that management must face these economic facts squarely. Any discussion of the cure for our economic ills that avoids facing these facts courageously, particularly the first and last—the fact that we are physically able to produce in superabundance and that the waste due to unemployment is the greatest of all industrial waste—cannot lead to a rational solution. We must be as courageous in our economic thought as we are in our engineering research; otherwise, we can expect nothing but continued confusion of thought.

Because we see the problem clearly, we need not assume that the sudden abandonment of all past economic traditions would be advisable. That would probably make the cure worse than the disease. But an engineer owes it to his profession to recognize fundamental facts. What action he takes after having ascertained the facts is a matter for sound balanced judgment.

Author's Closure

The discussion of this report on a decade of progress in management takes up two aspects: (1) interpretation and emphasis on certain items differing from that of the author, and (2) indication of a few developments mention of which was omitted in the report. These will be rediscussed in the order in which they appear in the preceding discussion.

Clark, Kimball, and Polakov stress the importance and enlarge upon the difficulty of national planning. Kimball emphasizes the change in the nature of the major problem confronting management engineers from that of production to that of distribution, saying that the new need "challenges the engineer and the industrialist." With all this the author is in complete sympathy.

Kimball and Kent comment upon the controversial topic of wages. The report does little more than present the aspects of the changing situation in the consideration of industrial wages and state the nature of the problems involved. No one can differ with the point of view that the entire matter is complex, difficult of solution, and of the utmost economic importance.

Kent, Wallace, and Eaton discuss technological unemployment, The divergences in their viewpoints indicate anew the need of a thoroughgoing study of this matter and of the related development and application of productive machinery. No greater contribution to our knowledge of economic processes could be made at this time than the findings of such an investigation. The temporary hardship suffered by individuals who lose their places in industry due to technical and managerial progress is a matter of common, continuing observation. The long-time readjustment whereby the same individuals find a new place in industry needs to be evaluated, before we can judge the probable extent of unemployment in any future situation. Kent calls the author to account for not showing that "mechanization of industry has created more employment for more people in the long run." While the author believes that is a true statement of what occurs, satisfying, quantitative evidence of the process is not available.

Kent comments upon the measurement of operating performance, saying, "The most important thing before management today is to learn how to evaluate itself and its own effectiveness." The author substantially agrees with this statement. If too little emphasis was placed upon this topic in the report, the lack is perhaps adequately made up in the paper which he presented jointly with J. E. Hannum on "Applications of the Kmh Method of Analyzing Manufacturing Operations" at the session of The American Society of Mechanical Engineers which received the Progress Report.

The author finds no reason to differ with Kent over his comments on budgeting and on shorter working hours. The trend toward the latter is unmistakable. Kent questions whether trade associations are intended to be included in the treatment of association and society activities. They are comprehended in the classification "business associations," and, as Kent remarks, they "may well become to an industry what the planning or production-control department is to the factory."

Polakov comments on the absence of reference in the report "to the influence of power production in the changing aims and methods of factory management." This development is not disregarded, for under the heading "Advance in Doing Work: Transfer of Skill," in treating of the increases in the physical volume of product is this statement: "The corresponding increase in utilization of primary horsepower per worker was some 30 per cent." Further, the question is quite properly raised whether the increase in primary power is not secondary to the development of productive machinery. As a reply to this query the author agrees with the point of view expressed in the following quotation from the Second Progress Report of the Committee on the Relation of Consumption, Production, and Distribution of the American Engineering Council: "The substitution of mechanisms, the transfer of human skill to machinery and tools, rather than the increased amount of power applied, is the essential change."

Bausch suggests: "Another item should be included as a part of the ten years' progress report and as an essential for recovery. This is unemployment insurance." Strong forces are gathering behind the proposals for unemployment insurance in some form. Under the heading, "Service Motive in Industry," reference is made in the report to this matter, and the enactment of laws to this end is foreshadowed: "Numerous bills to set up unemployment insurance may be expected to be introduced at the 1933 sessions of state legislatures. It will be surprising if some do not become law."

Mrs. Gilbreth in her comments takes up this matter of transfer of skill and gives an interpretation of the process in line with the most progressive modern thought. This topic deserves intense study that we may understand accurately what does occur both to man and machine when the process of transference takes place. This question groups properly under the broad heading of psychology which Mrs. Gilbreth urges for addition to the subjects in the range of interest of management engineers. The author strongly supports her suggestion.

Oberg challenges management engineers to face "economic facts squarely" and to be as "courageous in our economic thought as we are in our engineering research." He also gives eight "economic axioms" which formulate facts upon which management must build. The author accepts these axioms, as a presentation of the major features in our economic situation, and endorses the plea for courage in our economic thought.

MAN-55-3

Dissolving of Concentrated Industries

By HAROLD V. COES,[1] NEW YORK, N. Y.

Far-reaching changes in the pattern of industrial organization are discernible from the small changes that are now taking place in the evolutionary process of American industry. These changes, just discernible in some instances, seem to indicate the trend toward a better balance between urban and rural population, the development of new raw materials for industry and new sources for existing materials from agriculture, the location of industrial plants in agricultural communities to permit of lower costs and greater economic security for the workers, the greater use of branch plants and branch assembly plants to afford access to and to better serve the domestic market, a limitation of the concentration of industrial units in the large cities, and the dissolving of some of these concentrated units by scientific relocation to more suitable places. As the process goes on it should result in a better total economic balance, greater economic security to all, and more wholesome enjoyment of life by all. In bringing about and furthering these changes, the engineer, guided by economic and scientific facts, principles, and laws, will be an important factor and will play a leading part. More and more, and more than ever before, the engineer must become economic minded if he is to play his part well and serve society as it should be served.

General Statement of Problem

FAR-REACHING CHANGES in the pattern of industrial organization are discernible from the small changes that are now taking place in the evolutionary process of American industry. These changes, just discernible in some instances, seem to indicate the trend toward a better balance between urban and rural population, the development of new raw materials for industry and new sources for existing materials from agriculture, the location of industrial plants in agricultural communities to permit of lower costs and greater economic security for the workers, the greater use of branch plants and branch assembly plants to afford access to and to better serve the domestic market, a limitation of the concentration of industrial units in the large cities and the dissolving of some of these concentrated units by scientific relocation to more suitable localities. As the process goes on it should result in a better total economic balance, greater economic security to all, and more wholesome enjoyment of life by all. In bringing about and furthering these changes, the engineer, guided by economic and scientific facts, principles, and laws, will be an important factor and will play a leading part. More and more, and more than ever before, the engineer must become economic minded if he is to play his part well and serve society as it should be served.

During the early stages of the establishment and development of American industry, plants were located in small communities. The first instances of organized industrial activity on the American continent were the building of a ship by the Popham Colony in Maine in 1607 and of glass making at Jamestown, Va., in the same year. Neither of these industries developed or continued.[2] Industry was scattered; location was governed largely by the available water power. The steam engine as a prime mover was not an important factor. While the development of the steam engine rendered partially independent of water power those industries in which power was an important element, it was not until the advent of electricity as a prime mover in the early 80's that real concentration of industrial units began to take place. This was so even though steam and water power had brought about considerable concentration. Manufacturing then began to concentrate at those points where power generation and distribution were economical. This brought about concentration of labor, then labor specialization, until finally when the auxiliary and service industries moved in, we had concentration of industry as we now know it in large cities.

In the beginning of industry in this country, the workers in the factories were mainly agriculturists. Industry was frowned upon by the mother country, discriminatingly taxed, and discouraged before the Revolution. As industry became concentrated and specialized and labor more skilled and specialized, the tendency was to drop the farms and leave that work to others (as hours were long), until we ultimately arrive at the condition now confronting us in the large cities where the workers are absolutely dependent upon a pay check for existence. It is true that in some parts of New England, the Mid-West, and some other sections the workers still maintain their own homes and gardens and are to a considerable degree self-supporting during the periods of extended layoffs. In these communities one does not see the distress that prevails in the big centers of industry during a period of business recession such as the one through which we are now passing.

We have seen meat packing concentrated in Chicago, women's clothing in New York, tires and tubes in Akron, shoes in Lynn and St. Louis, automobiles in Detroit, silk in Paterson, woolens in Lowell, cotton goods in New Bedford and Fall River, men's clothing in Rochester, Cleveland, New York, and Chicago, and steel in Pittsburgh, Chicago, and Birmingham.

The Forces at Work

The factors and economic forces that brought this about are too numerous for discussion in this paper. They were generally availability of power, of raw materials, of skilled labor and craftsmanship, of markets, of transportation facilities, and of local capital. We are concerned here with the reverse of the

[1] Manager, Industrial Department, Ford, Bacon & Davis, Inc., Engineers. Mem. A.S.M.E. Mr. Coes was born in Hyde Park, Mass., on June 21, 1883. He was educated at Massachusetts Institute of Technology, receiving his B.S. in M.E. degree in 1906. He has been manager of Lockwood Greene & Co., Boston, Mass.; vice-president and general manager, Sentinel Manufacturing Company, New Haven, Conn.; Gunn, Richards & Co., industrial engineers, New York, N. Y.; Ford, Bacon & Davis, Inc.; vice-president and general manager, Belden Manufacturing Company, Chicago, Ill. He is president, Association of Consulting Management Engineers, and president, Institute of Management.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] Holmes, "Plant Location," p. 151.

process—dissolution of concentration. What is bringing this about? It seems to the author that two groups of forces are at work:

(*a*) Economic
(*b*) Sociologic

and heretofore the sociologic factors have been given relatively little attention. In the first group might be listed such factors as:

National rather than localized markets
Electrical distribution
Natural-gas distribution
Hard-surface roads
The automobile
The airplane
Communication lines
Trucks
Transportation costs
Better rail service—store-door delivery, container cars, etc.
Time of delivery to markets
Servicing
Automatic machinery
Wastes in distribution
Higher rents and values of land
Higher cost of operation in metropolitan areas
Higher taxes in metropolitan areas
Higher cost of labor
Higher costs of municipal government
Hazards of fire due to large concentrations.

In the second group are such considerations as:

Uncomfortable and bad living conditions
Health of wage earners
Racketeering
Municipal restrictions
Instability of labor
Hazards of plant-operation interruption due to concentration of large aggregations of labor
Insecurity of labor.

The operation of these factors is bringing about a diffusion of manufacturing capacity. The statement, "Present Distribution of Some Typical Industries" (see Table 1, Appendix), indicates to some extent what is taking place.

The author had occasion, several years ago, to study scientifically the cost of production of insulated wire in a large metropolitan area as compared with producing it in smaller suitable urban communities, and the total differential in cost of production and of distribution was about 25 per cent in favor of the most suitable of the smaller communities. Furthermore, the living conditions for the wage earners and their economic security were greatly enhanced.

The development of the electrical-power and natural-gas industries and of our railroad service, as well as our network of public highways, has given to plant location a new mobility.

The factors enabling this mobility away from cities began to emerge about 1910, chief of which was economical power generation and distribution to points well outside the large population centers. Manufacturing plants no longer have to locate in the large centers to secure cheap and reliable power.

Authoritative Statements on the Dissolving of Concentrated Industries

The Iron Age, January 15, 1931, page 221, makes these comments on industry dissolution:

The truly amazing development of products naturally occupies the foreground of any picture of industry's evolution. But back of the products, less obvious perhaps because of them, we may catch a glimpse of slower but far-reaching changes in the industrial organization itself. New cells are being added to this organism, old cells are being discarded, growth continuing with only occasional interruption. And in the process there is a distinguishable alteration of cellular arrangement, sufficient to bring about, say in ten-year periods, decided changes in the pattern of the organization as a whole.

Today it is not necessary for a factory to be next door to a power plant. Craftsmanship, handed down from generation to generation, is no longer a command to the plant to seek the community where skill exists. The development of automatic machinery has been gradually eliminating the factor of skill. And low-priced motor cars have done the rest by increasing the radius of the skilled worker. Transportation of raw materials and finished product is becoming less and less a determining factor since the motor truck has effected liaison with the railroad.

Our experience during this depression is likely to quicken the decentralization movement. Unemployment conditions were aggravated in those highly specialized industrial centers where like industries were concentrated. The least suffering occurred in communities where diversification was evident. A regrouping of industry made possible by its new liberty of movement might be of great social as well as economic benefit. Both plants and people get the least for their money in the big cities.

Mr. A. W. Robertson, Chairman of the Board of the Westinghouse Electric & Manufacturing Co., makes this statement in *The Iron Age* of the same issue, page 223:

Industry is seeking the open spaces and leaving the congested city factory district. Today, the factory finds it possible to escape from the city with its high rents and its uncomfortable living conditions. The springing up of the state-wide power networks and the development of automotive transportation have given industry a mobility which it did not have 20 years ago.

Most of our new plants are being built in uncongested areas. The industrial map of today is quite different from that of ten years past, and the coming ten years will bring still more diffusion.

Mr. Sidney G. Koon, associate editor of *The Iron Age*, in the issue of January 5, 1928, page 27, made a statistical analysis of the movement from East and West into the Indiana-Ohio-Michigan section. His study was confined largely to a comparison of rolled iron and steel production. In tabular form this analysis is as follows:

States	Date	Per cent of U. S. total	Per cent at end of 1927
Pennsylvania	1911–1914	49½	39
Indiana	1911–1914	6	13
Ohio	1911–1914	18	22
Ohio, Indiana and Illinois	1911–1914	34	42

Taking manufacturing in general and dealing with it on the basis of the total number of wage earners employed, the following facts appear:

States	Year	Per cent
New York, Pennsylvania, and New Jersey	1904	34
	1925	30
Ohio and Michigan	1904	10
	1925	14
Indiana and Illinois	1904	10
	1925	10½

He goes on to state that more than four-ninths of all products manufactured in the United States are produced in 68 cities, which had in 1920 a population of 100,000 or more. In some respects the study of production in the principal cities has yielded results similar to those cited. Taking the census figures for 1914 to 1925, inclusive, the cities showed their highest proportion in 1921 with 46.98 per cent of the total; their lowest came in 1925 with 44.81 per cent.

Mr. Martin J. Insull, in an article for the Engineering Foundation, appearing in *Electrical Engineering*, September, 1931, page 741, makes this statement:

By 1831, power had changed the decentralized industry of 1731 into a centralized industry. In 1931 power appears to be changing industry back into a decentralized structure—industry is not slow to recognize the advantages of decentralization in terms of lower costs and improved working conditions. In this there is hope for those who view with despair our industrial evolution. Let them not con-

clude that because we were headed toward industrial concentration for a century or more we cannot reverse the direction of our development. We need not necessarily expect still more congested cities, still higher skyscrapers, nor a depopulated countryside. The industry of the future is more likely to reinhabit the countryside, to possess all the advantages of power machinery without the disadvantages of congestion which have hitherto accompanied it.

Mr. George M. Verity, President of the American Rolling Mill Company, in an interview for *Electrical World*, May 12, 1928, page 973, comments on "Industrial Dissolution" as follows:

An outworn argument for the location of industries in so-called industrial centers has been that labor is plentiful in those centers. This is true. Labor of a kind is usually plentiful. But with that labor industry accepts the evils of a competitive labor market, of labor living in slums and less effective in consequence, of selfishly factional local governments, and of labor's disinterest in everything except wages. The plants of the American Rolling Mill Company are located in small cities. In these we know that the homes of our employees are brighter, more comfortable. We know that the eight hours of the day remaining after work and sleep are taken out are healthier and happier. We know that recreation is diversified and largely out of doors. We know that social life is at its best. We know that contact of our employees with community and municipal problems is closer and their participation in the administration of local government is on a broader and less sectarian basis. We know that the community of our employees is an important entity in the small city. We know these things because they are the reasons why our plants are located in small cities.

And finally:

Both employer and employed must develop an awareness of social duties, the performance of which will result in benefit to both. Nowhere but in the small town where relative size is greater can this condition be realized. This is why "Armco" is committed to the small town.

Mr. Henry Ford, in a paid advertisement in *Business Week*, June 22, 1932, advances this conclusion:

We are still in the early stage of world making. To stabilize conditions at a given point or to reject progress because it brings problems with it, is impossible. We need to plan how to pass through necessary changes with the least human hardship. Economic changes must come, and it is possible for men to be in a position to welcome, rather than dread them. With factory and farm as partners, with one foot on the soil and one foot planted on industry, we should be in a position to hail the new epoch without fear. The land would protect us from needless anxiety.

Comparison of Earnings of Large- and Small-Scale Industries

There is quite a popular impression that concentration is brought about by consolidation and merger, and that this is an economic necessity prerequisite to greater and more stable earnings. This impression, however, is not supported by the facts.

In the early nineteen hundreds many prominent economists wrote of the "important positive advantages," as expressed by one of them,[3] due to large-scale production. Another[4] announced that "modern production tends to become concentrated." It was not until a few years later than an economist expressed the idea that the concentration of production facilities was not necessarily essential to successful consolidation. He stated that the industrial factory must be limited in size for maximum efficiency, but that these limitations "applied with far greater force to a single local factory than to a federation of scattered plants. . . . The limits to the advantages of combination have been removed by the application of the federation plan."[5]

None of the writers ventured to suggest that there might be a point at which the law of diminishing returns would operate, a fact which would have a decided bearing on the limits of centralization and be a factor in the reverse process of dissolving concentration. The writers of that period, whether intentionally or otherwise, seemed to focus on the idea that size was the ultimate goal, the means to economic salvation, and it was inferred that there would be no place ultimately for the moderate-sized plant. Nothing, in the author's judgment, based on his observations and experience, can be wider of the truth. There are some products for some markets that lend themselves more readily to large-scale production than others, the producing units of which (i.e., individual plants or factories) can be on a larger scale for more economical use of large and expensive equipment. This does not mean that the whole production must of necessity be concentrated in one yard or plant.

Is there any evidence that individual plants of suitable size for maximum efficiency of operation scientifically located—the real core of the dissolving of concentrated industries—yield greater returns on the invested capital? A recent study by Prof. H. B. Summers, of Kansas State College,[6] sheds some light on this subject. He studied the earning records of 1130 companies over a period of 20 years, 1910 to 1929, inclusive, classified as follows:

		Companies
1	Iron and steel, including forgings, railroad equipment, and shipbuilding	139
2	Automobiles, including parts and accessories	82
3	Machinery, including heavy, light, farm equipment, office equipment, etc.	107
4	Hardware, including plumbing fixtures, electrical equipment, and specialties	82
5	Petroleum, including all branches of the industry	93
6	Chemicals, including pharmaceuticals, paints, and specialties	67
7	Textiles, including silk, rayon, cotton, woolens, linens, and heavy textiles	114
8	Foodstuffs, including baking, cane products, milling, fruits, packing, sugar	152
9	Miscellaneous, including building materials, furniture, glass, leather, lumber, paper, rubber, tobacco, and mining	294
10	Total all classes	1130

He first classified all companies in a size class (see Table 2, Appendix), then submitted a study showing average earning rates for all companies by size classification for the 20-year period (Table 3, Appendix), and then average earning rates by industries, by size classification for the 20-year period (Table 4, Appendix), and finally comparative earning rates, large and small companies, for the 20-year period (Table 5, Appendix), and he concluded as follows:

1 The highest rate of earnings for the 20-year period, all companies considered, is found in the smaller size group (see Table 3, Appendix).

2 Of the nine industrial classifications made, the highest average rate of earnings was found in the smallest size group, including companies with investment below $2,000,000 in five of the nine classes (see Table 4, Appendix).

3 In five of the nine classifications there is apparently a definite relationship between the amount of investment and long-time rate of earnings, with average earning rates decreasing as investment is increased. Marked variation from this tendency in earning rates is found only in the hardware group. In machinery manufacturing, there apparently is no relation between size of investment and earning power, and the same seems to hold true in the petroleum and miscellaneous industries classifications (see Table 4, Appendix).

4 Considering Table 5, Appendix, no matter where the dividing line is set, small companies when considered by industries, with four exceptions, show higher rates of earnings than large. If the dividing line is fixed at $2,000,000, the smaller companies show higher average earnings in each of the nine industrial classifications.

[4] Bullock, "Introduction to the Study of Economics," p. 178.
[5] Fetter, "Principles of Economics," p. 320.
[6] "A Comparison of the Rates of Earnings of Large- and Small-Scale Industries," *Quart. Jl. of Econ.*, May, 1932, p. 465.

5 With respect to any positive advantages accruing to large-scale production, the study offers nothing whatever in support of the idea that size in itself brings greater earning power.

The foregoing study has been given prominence in this paper, since the findings disclosed should have an important bearing on our thinking with respect to the problems of dissolving of concentration and would seem to indicate that moderate-size plants, scientifically located, have decided economic advantages in the long run. No attempt apparently was made in this study to determine the effect of proper location of individual units in a given industrial classification. If the companies compared in the paper of Professor Summers were studied from this angle, some very interesting and pertinent facts might be disclosed. We are indebted to him for the facts he has so thoughtfully brought to our attention..

In the study of economic changes in the United States by the National Bureau of Economic Research, a table is presented showing in specified states the increase and decrease in manufacturing.[7] (See Table 5, Appendix.)

This shows a marked decline in manufacturing and establishments in the larger cities for the period reviewed, 1919 to 1925, inclusive, particularly for the so-called industrial states, and also a decided trend toward industrial growth in towns of less than 25,000 population and in agricultural states.

In commenting on the trend toward dissolving concentration, the writer makes these statements:

> It seems quite conceivable that the newer agriculture will tend to maintain a skeleton force on the land and transfer labor from town to country to meet seasonal requirements. . . . The easier way seems the shift of tractor men and practically unskilled harvest hands into the country during short periods of special needs, with the same groups productively fitted into industrial callings of the town during agriculture's slack season. . . .
>
> All in all, it seems that the hard and fast line between agriculture and other industries and between rural and urban residence will tend to disappear. . . . A tendency is noticeable among some manufacturers to get their plants distributed in towns and villages adjacent to agricultural land. . . . It is impossible to show this approach of manufacturing toward the agricultural regions by statistical methods with as much clearness as could be desired. But it is apparent from the census of manufacturers over the last few years that a drift away from the highly industrialized centers in the Northeast and toward the smaller towns and villages in the Central, Southern, and Western states has been under way. . . .
>
> That the rapprochement of city and country which appears to be under way in response to new conditions of auto transportation and to the organization of both farm and factory work, holds the possibilities for improved conditions on both sides. . . .

Plant and Branch Plant Relocations

In a cooperative survey by the Civic Development Committee of the National Electric Light Association and the Policy Holders Service Bureau of the Metropolitan Life Insurance Company, entitled "Industrial Development in the United States and Canada, 1926 and 1927," 1934 communities in the United States were studied, reporting over 10,000 plants and 371,000 workers gained in that period by the reporting communities. Plant relocations accounted for 9.4 per cent of the plants and 18.7 per cent of the employees. New industries accounted for 81.8 per cent of the plants and 56.3 per cent of the employees gained, while branch plants were responsible for the remainder of 8.8 per cent of the plants and 25 per cent of the employees. The average size of plants gained for the country as a whole was 36 employees. The average relocated industry had 71 employees and the average branch plant had 103 employees. The average new local industry had 25 employees.

The reasons in the order of their importance for all gains for the United States as a whole are shown by the following list (see Table 8, Appendix):

1 Markets
2 Labor
3 Transportation
4 Materials
5 Available buildings
6 Power and fuel
7 Near related industries
8 Living conditions
9 Financial aid
10 Taxes
11 Consolidation
12 Laws
13 Disposal of waste.

Selecting arbitrarily 50,000 population as the dividing line between larger and smaller cities, the survey shows that the larger cities gained 58.4 per cent of the total employment gains and 73.1 per cent of the total plants. (This reflects the process of concentration.) They give as the reasons for this the large number of "satellite" industries which are established around existing industries located therein and the development of style industries in clothing and related groups in metropolitan areas.

They point out that the extent to which smaller cities have gained through establishment of branches and relocations within their borders is worthy of special note. Of all gains made by these cities, those under 10,000 in population received 26.2 per cent of all branches reported in the survey and 17.9 per cent of the locations. (This shows the principle of decentralization at work.)

The percentage of the total gain in cities, classified by population, is as follows:

Cities of	Per cent
150,000 or over	39
50,000 or over	21
10,000 or over	21
2,500 or over	13
Under 2,500	6

The United States Chamber of Commerce also made a study of branch plant establishment and location, the facts concerning which are summarized in Table 9, Appendix.

The use of branch plants as a means for industrial expansion and dissolving of concentration is a comparatively recent development and is primarily the direct result of the operation of economic forces, particularly in the field of marketing and service.

It will be noticed that the diffusion is largely in the Middle Atlantic, East North Central, and the Pacific States divisions. The largest number of branches with headquarters outside of the division are located, first, in the Pacific division and, second, in the South Atlantic division.

The same study provides some information as to the size of the branches established, on the basis of wage earners employed, as follows:

Wage earners	Number of branches
1 to 5	17
6 to 10	33
11 to 25	53
26 to 50	40
51 to 100	34
101 and over	41

There is evidently a trend toward more equal distribution of manufacturing in many industries throughout the country.

Some light can be shed on the large city dissolving of concentration by studying the shift of wage earners between cities and urban localities, as discussed in "Recent Economic Changes:"[8]

Between 1919 and 1925, while the 25 largest cities in the country lost 326,800 wage earners, about 12 per cent of the average number

[7] "Recent Economic Changes," vol. 2, p. 591.

[8] Ibid., vol. 1, p. 210.

employed, the rural area (all area not included in communities having a population of 10,000 inhabitants) gained 55,204 wage earners. Nor is this decrease limited to the larger cities. Cities between 100,000 and 250,000 population lost even more heavily, 14 per cent of their wage earners, communities between 25,000 and 100,000 lost 11 per cent, and those between 10,000 and 25,000 lost 8 per cent of their wage earners.

The United States Chamber of Commerce made a study of this subject as well, and the findings are summarized in Table 10, Appendix.

As evidence of the changes in concentration, the following is of interest:

AVERAGE NUMBER OF WAGE EARNERS PER ESTABLISHMENT BY SIZE OF COMMUNITY, 1919 AND 1925[9]

Population of community	1919[a]	1925
Over 250,000	35.7	35.1
100,000 to 250,000	60.6	56.7
25,000 to 100,000	63.1	64.0
10,000 to 25,000	52.9	57.9
Remainder	31.0	42.3

[a] Corrected for establishments with product under $5000, but not for "automobile repairing" or "coffee roasting," both of which were included in 1919 and not in 1925.

Additional evidence of the dissolving of local concentration of industry is shown by the following computation:

DISTRIBUTION OF 105 INSTANCES OF LOCAL CONCENTRATION[10]

(According to the census date at which the community reached its highest percentage of the national total)

1899	32
1904	21
1909	15
1914	4
1919	14
1923	9
1925	10
	105

This was obtained "from examining all cases for which continuous records were available since 1899 for communities which at some time produced at least 3 per cent of the national product in some industry. In this way it was possible to obtain records for 105 instances of local concentration. The percentage which each community was of the national total was then computed for each census date to determine whether it was gaining or losing in relative position. . . . It is quite conclusive that one-half the cases examined reached their highest point by 1904, and that but 10 of the 105 were at their highest point when the record ended."[11]

The Shift in Population

The shift in population from rural to urban in the United States can be seen from Table 11, Appendix. In 1870, 79 per cent was rural and 21 per cent urban; in 1900, 40 per cent was urban and 60 per cent rural; while in 1930, the urban population was greater than the rural, 56 per cent being urban and 44 per cent rural.

Table 12, Appendix, shows the shift by major geographic divisions from 1880 to 1930, inclusive.

Factors That Will Assist Toward the Dissolving of Concentrated Industries

That dissolving of concentration of industry is taking place is evidenced by the policies pursued by several large companies. The Ford Motor Company builds assembly plants at suitable points to serve its various markets throughout the country, a decentralization of some of its manufacturing and assembly operations. The General Electric Company has a policy of acquiring or building new plants for new products, rather than concentration of manufacture at Schenectady. Dissolving of concentration is also brought about by the economics of distribution and marketing, resulting in many companies locating branch plants at strategic points to better serve their markets.

What has probably not been realized, up to the present, is the menace to society as a whole from large masses of workers thrown out of employment and with no visible means of support. We must learn to plan better. When we realize the fundamental relationships between the support of workers from the land and from industry, or, as Mr. Ford puts it, with factory and farm as partners or factory and suburban gardens as partners, then perhaps accelerated dissolution of concentration will take place to the lasting benefit of workers, employers, and society.

Modern means of transportation and communication permit centralized control of isolated units. With teletypes, and now with television just around the corner, this control will be rendered speedier, easier, and more satisfactory.

Local advantages become increasingly less important with increased facilities in transportation and greater mobility on the part of industrial workers. This is so markedly true that the problem of locating any new industry has become one of economic consideration into which many factors must enter.[12]

Studies of wastes in distribution will probably be a real factor in dissolving industrial concentration. If it is true, as some of us believe, that our production technique is far ahead of our distribution technique and that improvement in production technique is reaching the point in many instances of diminishing returns, then manufacturers in the future must look for their profit in better distribution technique and the elimination of many of these distribution wastes. This means that scientific plant location, branch plant location, etc. will be the order of the day and that plant locations will be chosen with a scientific regard for the factor of distribution. It is a significant fact that scientific marketing analysis and marketing has measurably lagged behind scientific production methods.

It is believed that in the past too much weight has been given to population as a basis for distribution. Mr. Holmes makes this observation:

> It has often been pointed out that manufacturing goods cannot be sold to square miles of land. Neither can they be sold to thousands of people. The theory that population is an index of the market for manufactured commodities is false. No one article is consumed or one service purchased precisely according to the distribution of population. The potential market for a manufactured product depends upon many different factors.[13]

Scientific marketing then will bring about the dissolving of industrial concentration.

There is still another factor that must receive more study and attention than it has, and that is the decreasing number of man-hours required per unit of production. Prof. Walter Rautenstrauch of Columbia University cites some figures in connection with the 100-year energy survey being conducted by Columbia University at the present time, which shows the trend in some industries:

Product	Date	Man-hours
Cement	1905	1.75 per bbl
	1930	0.45 per bbl
Automobile	1904	12.91 per car
	1929	9.2 per car
Steel	1900	7.0 per ton
	1929	1.3 per ton

These studies so far indicate that employment reached its peak in 1918 and has declined ever since, while production reached its peak in 1929.

[9] "Recent Economic Changes," vol. 1, p. 213.
[10] Ibid., p. 215.
[11] Ibid., p. 215.
[12] Kimball, "Industrial Economics," p. 62.
[13] "Plant Location," p. 21.

This would indicate a declining employment rate in basic established industries for normal consumption, and in the absence of a new industry to take up this slack in employment, such as occurred when the automobile and radio industries were born, or without increased consumption of the products of these basic industries, we have in so far as spreading employment is concerned, a real problem to solve. To what extent we can solve this problem by the partnership of the land and the factory and by a greater knowledge of consumer demands and preferences is not now clear. That it must be solved, however, is quite clear.

The author believes there are illimitable possibilities in the proposed research in agriculture to produce perennially for industry many of the raw materials it needs and many new ones. There should ensue much desired diffusion of labor to extraction plants in the agricultural districts which would further bring about as a concomitant result, in all probability, dissolving of industrial concentration.

Just what part safe and inexpensive airplanes may play in the dissolving of industrial concentration and in widening the radius of activity of industrial workers is difficult now to forsee, but it is conceivable that it might extend their radius and their mobility almost as much over the automobile as the automobiles did over the horse and buggy. We could then visualize ourselves as living on a farm or in an agricultural community 100 or more miles away from our offices and require no more, or perhaps less, time to commute than we now take. The factory could readily be 100 or more miles from the office, located in a large city, and yet be readily accessible.

That there will be a drift away from the large centers, both of industry and of people, to points where both can enjoy the benefits of relatively unconfined space is the author's firm belief.

Conclusion

The foregoing authorities have been cited to show the trend of thinking—the conclusions that some of them draw.

There is then sufficient evidence for one to come to the conclusion as a result of economic and sociologic forces that our industrial pattern is undergoing a change. There is a growing consciousness that after all there are no such beings as supermen; that perhaps there is a limit to man's comprehension; that maybe we can get physical units too big and aggregations of employees too large for sound and efficient administration and management. We are realizing that cities can become too large for comfort, well being, and safe and efficient administration; that the advantage of a large city location for industrial units, except for those organizations which must of necessity be located in or immediately adjacent to a metropolitan area, can be more than offset by the disadvantages.

Again, there is a growing consciousness of the economic insecurity of masses of our population living in the large cities whose sole dependence is on a regular pay check, and that while business continues to move in cycles, whole sections of the population can and are temporarily at least dislocated, disorganized, and in distress; that this imposes huge burdens on the employed population, the employers, the city welfare organizations, the city administration, and the state—sometimes, as at present, greater than their resources can sustain—and that therefore we have thrown our rural and urban population out of balance. (See Table 11, Appendix.)

All of the foregoing considerations are leading thoughtful men and women to the conclusion that we can best bring our population into balance, strengthen our economic position, and bring more light and happiness into the lives of thousands of families if the process of the dissolving of industrial concentration is speeded up.

Appendix

The statistical matter referred to in the text upon which the author has based some of his conclusions is contained in this Appendix.

TABLE 2 CLASSIFICATION OF COMPANIES BY SIZE

Size class	Including companies with permanent investments ranging		
1	Less than		$2,000,000
2	From $2,000,000	to	$5,000,000
3	From $5,000,000	to	$10,000,000
4	From $10,000,000	to	$25,000,000
5	From $25,000,000	to	$50,000,000
6	From $50,000,000	to	$100,000,000
7	More than		$100,000,000

Discussion

DEXTER S. KIMBALL.[14] The paper presents in an excellent manner a belief that has been growing in the minds of many students of industry for some time. The author's presentation is convincing, not only as to what is really happening, but what should happen for the good of all concerned. Many students of industry have pointed out the manifest disadvantages of highly concentrated industry, but it has remained for this great depression to impress upon us more vividly than ever the evils of extreme industrial concentration in bad times. A visit to any great manufacturing center, such as Detroit, leaves one distressed beyond words and wondering how such calamities can be prevented. And it is little wonder that men like Mr. Ford have begun to doubt the merits of vast size and high concentration. In the writer's opinion the author is quite right in his conclusions, and it is not believed that we shall see again such vast integration and consolidation as we now have in some of our mass-production industries.

Aside, also, from these human considerations, there is good reason for believing that the economic considerations which the author quotes will receive ever-increasing consideration. While he does not refer to it specifically, he indicates that the old law of diminishing returns applies here as elsewhere. It has been generally assumed that the larger the manufacturing unit the lower may be the cost, but there is no reason for thinking that this is true indefinitely as the size of the plant increases. There must be a maximum size for any given plant beyond which costs increase rather than decrease, or else the old law of diminishing returns is false, and so far we have known no exceptions to this law.

Unfortunately, we have no quantitative studies bearing on this problem. If large industries possess data bearing upon it, they have not published them. The United States Census Reports show that the per capita value of manufactured products has risen steadily as our industrial machinery developed. But the ratio of the value of manufactured products to the capital invested has declined steadily. In 1850 this ratio was close to 2, and it has declined steadily ever since, being 1.39 in 1919. We are in need of statistical data on the relative efficiency of manufacturing plants of varying sizes, and the writer is confident that if such data could be secured they would verify fully the author's conclusions.

J. C. HECKMAN.[15] Statistics on this subject are necessarily fragmentary, and when viewed separately can scarcely be relied upon as a basis for general conclusions. But the group assembled here by the author supplement each other impressively to establish a very definite trend.

[14] Dean of Engineering, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

[15] Larchmont, N. Y. Mem. A.S.M.E.

The concentration which took place in the early days of our industrial development was effected in direct opposition to the direction of growth in the country. Until that time the development had been agricultural, and there was a continuous spreading out of the population into freshly opened lands farther and farther westward from the settlements.

Evidently, powerful forces must have come into play to arrest and in a measure reverse this flow of population. The forces which did this were the forces that caused our rapidly multiplying manufacturing plants to be established in the larger communities and in districts where their particular industries were already operating. Principal among these forces were:

1 Cheap or convenient power supply
2 Proximity to skilled labor already trained in the industry
3 Proximity to supplies of raw material
4 Proximity to local markets.

If, as the author's statistics clearly indicate, there has been a marked swing away from this movement of concentration, it must follow that some change has occurred in the strength or direction of the forces that previously favored this movement.

In considering the data presented, it must be borne in mind that they represent only new manufacturing plants or branches of old plants established in recent years. Established businesses having reasonably modern and efficient plants are held to their present locations by bonds too powerful to be readily severed. If the figures are studied in relation to the total new plants established during the period rather than in relation to our total manufacturing plants, they acquire added significance.

Consider the present characteristics of the factors already mentioned as determining the original concentration of our industries:

1 Power at a reasonable cost is no longer the possession of a few localities or confined to the larger towns and cities. The development of interconnected power networks covering such a large part of our country makes power widely obtainable at lower costs than ever before. Notwithstanding the large increase in power used per employee, only those new plants using very large blocks of power or those in which power is produced as a by-product of the manufacturing process can afford now to build and operate new isolated power plants.

2 The factor of proximity to skilled labor has also lost much of its force, partly because skilled labor is much more widely diffused than it used to be, but mainly because the development of automatic machinery, much of it peculiar to an industry or even to an individual plant, obviates the need for skilled labor, in its old sense, in production work and makes it necessary and economical for plants to train their own production employees. A distinction must be made between skilled labor and what may be called production labor. The existence of a potential supply of labor capable of being trained to efficient production, within living distance of the plant, is of course essential to all manufacturies, but this requirement may be met in a location not in a large city or town and not adjacent to other allied industries.

3 The factor of proximity to raw materials is really but one element in the general factor of transportation which includes not only the transportation of raw material to the plant and the transportation of the finished products to market, but also a frequently overlooked item involving the transportation of all the living supplies of the manufacturing community to the homes of the families of the employees. All three elements eventually enter into the delivered cost of the finished product and must be considered in the complete analysis. We are all familiar with instances of industries that originally centralized in certain districts because of proximity to raw materials and have long continued to flourish there after the raw materials have been exhausted or have been replaced by cheaper or better supplies from other districts. With the development of means of transportation, except in the case of some special industries using large tonnages of low-priced raw materials, proximity to raw materials has ceased to be a determining factor in plant location. And even in these cases it is the location on a good transportation system from a source of supply rather than proximity to the source itself that is important.

4 It is significant that Table 8 in the Appendix to the paper, giving the relative importance of the factors in plant relocation, reveals markets as the factor of leading importance in choosing such locations. With the expansion of industries into national and international distribution, local markets have receded into a less important position. Locations have to be chosen with consideration of the broader field. Prompt customer service as well as transportation costs have also become an importnat factor. As the country has become more widely settled, this factor of markets has reversed its direction and has become an important one in the dissolving of industrial concentration.

It is apparent, therefore, that the facts of industrial deconcentration that the author has brought to attention are the result of a definite realignment of economic forces. It might be added that this new alignment not only permits but aids what we hope is the natural trend of people away from the crowded dwelling places of congested cities.

The author says that the forces at work may be divided into two groups—economic and sociologic. For purposes of analysis and discussion this is a useful division. In actual application it is difficult to draw a sharp line between the two groups. As engineers we perhaps are out of our field in discussing sociology. But we have learned that sociologic factors have a profound effect on economic results. The conditions under which our employees live have a marked effect on their efficiency and ultimately on the costs of their product.

For us as engineers who may be called upon to advise on specific cases of proposed new or branch plant locations, it may be sufficient to accept the conclusions of this paper that the sociologic results of dissolving industrial concentration are beneficial to the country as a whole and be appreciative of the conclusion that they reinforce the economic forces. A sociologist might prefer to reverse that statement and put it that it is fortunate that the economic forces act in the same direction as sociologic progress.

We all know that in most manufacturing processes there exists a maximum-sized economic unit. The actual size varies greatly with the process involved. It may be small in a simple process or very large where automatic machinery of tremendous capacity is necessary for greatest economy.

In a small business where clearly only one unit is justified by the size of the business, obviously only one location can be considered. But after market studies and other considerations have settled the question of the proper district in which the location should be made, the question still remains whether the location should be in a large or small community and whether to locate near a similar industry or not. It is at this point that the factors presented in this paper call for consideration.

With larger companies the major question of branch plants at once arises. Shall or shall not branch plants be established? If so, how widely shall they be distributed? Shall they be merely assembly plants or complete factories? Shall they make a considerable portion of the company's complete line or shall they be special units making a few allied products? A host of such questions suggest themselves.

Obviously a general solution cannot be offered. Each case is a subject for special study. But in each case if separate plants are decided on, the same decisions have to be made as to the size and type of community in which the plants shall be located.

One point may be emphasized. A group of branch plants cannot be successfully operated without an efficient central modern planning, control, and administration system.

However strong the trend, it is evident that no rapid transition to a wider distribution of our industrial plants is possible. The inertia of existing conditions is too great; the capital invested in existing plants is too tremendous. But to those of us who feel the disadvantages of existing conditions, with crowded urban populations absolutely dependent, as the author puts it, on the weekly pay envelope for existence; to those of us who believe that a better balance between urban and rural population is necessary for the best interests of the country—the marked trend toward the dissolving of concentrated industries as shown in this paper is most heartening for the future.

W. S. Giele.[16] The writer has had the opportunity to observe at close range certain phases of the process of the dissolving of concentrated industries and also to contrast the operation of plants in large cities and in small communities. Points bearing directly on the paper can be illustrated by data and observations from Lebanon, Pa. The population of Lebanon county in 1930 was: Total, 67,103; urban, 32,513; rural (non-farm), 23,590; rural (farm), 10,982; employed, 26,735. The industries were:

	Manufacturing	Agricultural
Value of products	$43,276,700	$6,308,560
Capital invested	$26,041,500	$19,341,406
Persons employed	10,705	....
Compensation	$10,032,400	....

Among the plants brought to Lebanon by the Chamber of Commerce from congested metropolitan districts were plants manufacturing or processing cigars, clothing (men's), clothing (women's), handkerchiefs, hosiery, rayon, shirts, shoes, and silk.

Among the industries which originated in a semi-rural environment are the Hershey Chocolate Company, the Lebanon Paper Box Company, and the Lebanon Steel Foundry, producing small steel castings of special alloys. All of these industries found that with modern transportation and communications facilities they could remain in sufficiently close touch with their markets. The Lebanon Steel Foundry, which does its melting in electric furnaces, is an example of what the distribution of power has made possible. All of these industries find material savings in many of those items in the cost of doing business that are incidental to congestion.

However, the greatest single advantage gained by all lies in the greater economic security, better living conditions, and general well being of the workers. Improved roads and cheap automobiles have increased the radius from which workers can be drawn, and many of these plants collect workers in buses. These people have been rooted in the soil for many generations. Shorter factory hours or lack of factory employment give them opportunity for agricultural activities. They have shelter and fuel and food.

An important factor, and one seldom mentioned, is that the wider distribution of power and of mechanization has affected the farm as well as the factory. The great reduction in man-hours (and in woman-hours) required to do farm work constitutes a reservoir of potential labor supply so located that industry will have to go out to meet it. This is a labor supply that can maintain itself in times of industrial depression and relieve in some measure a part of the farm problem in that these people eat the food where it is produced.

The Hershey Chocolate Company has developed a combination of industry with agriculture that seems nearly ideal. The farms surrounding its industrial community produce the milk that goes into the product, and the farm boys and girls work in the factory.

The relatively lower cost of workingmen's homes, with the relatively greater stability of real-estate values, contributes to the sense of economic security in the smaller communities.

Lastly, the laid-off worker comes in contact with opportunity for new employment much more readily in the smaller communities than he does in the more concentrated areas—another factor in economic security.

Harry Arthur Hopf.[17] The concentration of industrial plants in cities of this country has already exceeded all limits dictated by a decent regard for living conditions, wage levels, transportation facilities, health, law observance, and the rearing of children. In the mad desire for profits the welfare of human beings has only too often been subordinated to monetary considerations. While it is of course absurd to suppose that complete decentralization of all manufacturing enterprise is an objective to the attainment of which our best energies and abilities should be dedicated, we may in all fairness assume that the highest dictates of enlightened social policy support acceleration of the trend which is discussed in the paper.

Lewis Mumford, critic of architecture, stated in one of his books substantially as follows: "We cut a steel gash in the bowels of the earth and call it a subway. Every morning we hurl from the Harlem to the Battery, within a concentrated period of time, several hundred thousands of people under disgraceful conditions of crowding. Every evening we repeat the process in the reverse direction, and that is what we are pleased to call civilization."

In the background of the entire discussion to which this paper is devoted is the challenging question, "How big is too big?" In all human undertakings we must strive to find the optimum of size, and that applies to cities, states, and governments, to industries, schools, and churches, and even to many other things. If the trend to decentralization of industry will ultimately result in more normal conditions of human life and happiness, it is a secondary consideration whether or not the highest profit possibilities may be achieved under such circumstances.

H. R. Taube.[18] The author has analyzed the economic forces and considerations which in many cases justify the transfer of existing industrial plants from congested cities into smaller communities or the establishment in them of branch plants or new enterprises. His arguments in regard to the sociological advantages of the dissolution of concentrated industries seem, however, less convincing. He mentions, for instance, "the hazards of plant-operation interruption due to concentration of large aggregations of labor," alluding evidently to labor disputes, strikes, etc. As a matter of fact, the last ten years, comprising periods of intensive industrial activity and of unprecedented depression, have been, as far as the highly concentrated large-scale industries are concerned, conspicuously free from such disturbances—a result that must be credited primarily to the far-seeing, progressive management of these industries. The news of serious labor conflicts that during these years appeared on the front pages of the metropolitan press did not come from Pittsburgh, Cleveland, or Chicago, but from the mill towns of North Carolina and from the mining towns of the soft-coal districts of Kentucky and Illinois, where they, theoretically, ought to be least expected. These labor disturbances, characterized by violence and bloodshed, have more than once required the calling out of troops and found an aftermath in sensational murder trials.

[16] Mechanical Engineer, Philadelphia, Pa. Mem. A.S.M.E.

[17] H. A. Hopf & Co., New York, N. Y. Mem. A.S.M.E.

[18] New York, N. Y. Mem. A.S.M.E.

Reports of these events in the New York "Times," a paper that can hardly be suspected of radical tendencies, have revealed most shocking living and working conditions prevailing in those small half-rural communities—conditions which compare unfavorably with those in large industrial centers.

The author, pointing out the declining rate of employment in the basic established industries, remarks that "we have in so far as spreading employment is concerned, a real problem to solve. To what extent we can solve this problem by the partnership of the land and the factory . . . is not yet clear." The possibilities of solving the unemployment problem in this way seem very remote indeed. Industries that can be set up in strictly rural districts and can rely upon the employment of farm labor available during the winter months are rare exceptions rather than the rule. This is borne out by the statistics on the fourth page of the paper. The number of industrial plants gained in the years 1926 and 1927 by communities having a population of less than 2500 is only 6 per cent, as against 60 per cent in cities of over 50,000. The benefits to be derived from gardens made available to industrial workers in smaller communities are also very limited. Taking care of these truck gardens might promote the health and morale of the workers and the produce they grow might reduce their grocery bills, but they cannot provide economic security, particularly so if the worker does not own the land and might be dispossessed at any time.

It is therefore difficult to see how the transfer of industrial plants into small or rural communities can protect the wage earner from the results of cyclical or casual unemployment, whereas in regard to technological unemployment he is decidedly worse off than the worker in industrial centers offering opportunities for employment either in other industries or in other occupations. The plight of the miners in the soft-coal districts is a good illustration. While unable to earn a living wage in an overmanned and disorganized industry, they cannot get away from it, lacking the knowledge, the mobility, and the opportunity to make their way into other occupations.

There is still another side to this question. As a rule, when a plant is transferred to a new location, only a limited number of indispensable highly skilled men is taken along, and the rest of the new labor force is recruited from local labor, part of which is drawn from non-industrial occupations. Thus the supply of industrial labor is increased, whereas industrial employment, since 1919, has been steadily declining. The final result will be an increase in the number of the permanently unemployed industrial wage earners. A speeding up of the process of dissolution of concentrated industries, advocated by the author, might therefore noticeably aggravate the already serious unemployment situation.

From the facts presented so impressively by the author and from those mentioned herein, three conclusions might be drawn:

1 The dissolution of concentrated industries offers in many cases to the individual manufacturer distinct economic advantages; we do not, however, possess at the present time sufficient data to judge how this process, applied on a large scale and carried out in a brief period, might affect industry and national economic life as a whole—for instance, to what extent the lowering of wages, which is one of the main factors in favor of decentralization and plant relocation, might narrow the market for industrial products.

2 The possibilities for sociological improvements inherent in decentralization do not come into effect automatically; better living conditions of the worker and industrial peace do not depend so much on the size of the community as on the type of management and the character of its policies.

3 Dissolution of concentrated industries does not provide a palliative for, let alone a solution of, the most pressing industrial problem society is confronted with—that of unemployment.

JOHN A. PIQUET.[19] The decentralization of manufacturing is not a theory nor an attempt at utopia. Facts show, first, that it is going on quite rapidly; second, that decentralization should increase more rapidly than ever, and, third, that its effects are beneficial to all interests. The paper brings out two of the most important factors in industrial decentralization:

1 That the small or medium-size industry can compete favorably with the large corporation. This is important, for the cause of the concentration of industry and population in large cities and in one small section of the country, the Northeastern States, has been largely the control under few hands of the technical knowledge, capital, and industrial facilities of the nation. These relatively few industrialists and financiers have by force of the limitations of time and distance desired to keep the factories near their offices—in short, in relatively few places and sections. Furthermore, large or mass-production plants have favored a location in large centers where mass labor supply, nearness to large banks, the best water and rail facilities, etc., are present. The argument that real decentralization of industry can come about through large corporations establishing myriad branches throughout the nation is not sound, as there is a limit to such branches due to the serious fluctuations in sales suffered by large corporations, the difficulty of keeping track of many branches, and other handicaps that big manufacturers suffer.

2 That the small city, with the extension to it of power, truck transport, educated people, telephone, radio, amusement, and in short most or all of the business and living conveniences once monopolized by the large cities, is now in a position to handle industrial production efficiently, while having lower land, tax, and living costs than the big cities, and hence better for labor morale and factory costs.

The concentration of manufactures in this country is very great, and has led directly to high costs in shipping raw materials long distances from every part of the nation to the Northeast factories, in shipping finished goods long distances, in the necessity for armies of salesmen, branch depots, jobbers, and swollen retail sections in every town; in huge advertising totals; in the high cost of financing this long-distance and highly competitive distribution; and finally, in labor troubles, crime-breeding slums, inefficient factories and layouts, high land and tax costs, and other evils of crowded industry in large or one-industry cities.

The Northeast, the section extending from Boston to Chicago and north of the Mason and Dixon line and the Ohio River, has held its own in industrial concentration, although its share of the nation's population has decreased, thus:

	Per cent of United States Population	Per cent of United States Manufactures (value)
1900	63	83
1927	49	71

This indicates an approximate increase of about 5 per cent in concentration, allowing for the higher value of the finished products made in the Northeast over the large percentage of semi-finished products made elsewhere. This increase in concentration is directly due to war and boom production and expansion since 1916, the quick demand for more goods being accommodated largely in the Northeast with its already large and numerous factories, and the control of war and boom orders by companies operating mainly in the Northeast.

The other side of the picture—decentralization—is shown in many figures and many trends, of which a few are as follows:

First, within the Northeast itself, highly concentrated industrial centers and state are losing production to smaller places or other states in the region. The decentralization of centers of

[19] Metropolitan Information Service, New York, N. Y.

three basic manufacturing industries in percentage of national production is shown as follows:

	State	1900, per cent	1927, per cent
Iron and steel.....	Pennsylvania	54	39
Cotton goods.....	Massachusetts	32	18
Meat packing.....	Illinois	40	22

The story back of these figures is well known. Blast-furnace and rolling-mill production gradually concentrated around Pittsburgh, then decentralized toward markets, at Chicago, Cleveland, Baltimore, Detroit, with small centers developing in Utah, on the Coast, at Lake Champlain, Troy, Boston, Newark, and of course the raw-material and market combination of Birmingham. Ala. Cotton goods spread throughout the South, for labor reasons. Meat packing extended from Chicago to Kansas City, Cincinnati, and now into every section of the country where cattle and hogs can be conveniently gathered from a radius of 200 miles, and particularly where growing markets abound. Cement, once made near Allentown, Pa., and shipped as far as Texas, is now produced in every section of the country. The same story goes for the coarser grades of paper, once concentrated in New England. Sugar refining, originally a New York monopoly, is scattered in every principal port from Boston to New Orleans. Cracker bakeries, once concentrated, are now found in all chief centers. Tin cans are now made in every large center, or near every important source of sea foods, fruits, or vegetables. The same goes for canneries of all sorts, their location being dependent on the raw material rather than on the market. Flour mills have extended from Minneapolis through to Buffalo. Minor trends which are not important yet, but of interest, are the home flour mills sold to families following the movement for using the original flour with all its food values which commercial white flour eliminates in part, and the barter movements of the present business depression, where farmers in many sections are having their own flour ground at local flour mills of small size.

The clothing and garment industries, once so highly concentrated in New York, have established over a thousand plants in small towns in the Northeast since the war, for labor reasons. Fine silk underwear, a style product, is slowly leading the way in the trend from Broadway locations (so essential to style products because of frequent changes in style and desires of visiting store buyers) to smaller cities, for labor reasons. Standard goods, like men's clothing, shirts, rayon and cotton underwear, and work garments, are well decentralized. Printing of books, monthly magazines, and large jobs is becoming a small-city proposition due to the strong unions of the large centers. The postal rates on printed matter by mileage zones have also tended to move much Eastern printing and paper patterns and other printed matter to factories in the Middle West, mainly in small cities—a central location for national distribution. Shoes and slippers are steadily extending from large cities to small towns, for labor reasons, and from their original New England home to Missouri, Pennsylvania, and many other states. Candy making follows population so closely that in addition to large plants in large cities everywhere, we also have myriad small plants, located in every town. Freshness is a factor, while the capital required to start is small. Silk weaving, tied closely to New York by selling and financing reasons, is nevertheless now a small-town industry, due to labor costs, and is scattered in localities from Massachusetts to Maryland, with Pennsylvania the leader. Full-fashioned silk hosiery is slowly scattering in small cities throughout the East, for labor reasons, while the still concentrated carpet and upholstery firms of Philadelphia are making surveys of country towns in the East and South with a view of eventually escaping the combination of high labor and high taxes. Narrow fabrics and lace curtains are other Philadelphia industries that are tending toward smaller cities.

Finally, almost every large center has extended its definitely suburban areas of industry until some of them reach as much as 60 miles out. In New York City the total gain in number of industrial employees since 1914 has been in New Jersey, adjacent to the metropolis; the actual number in the city has remained the same. Despite this decentralization, New York City and its area still remains so powerful an example of the extreme concentration of industry that here are manufactured more goods, in value, than in all New England or in all the South east of the Mississippi River.

Because industry is tending to follow population so closely, it is interesting to note that the Northeast, with its 49 per cent of population and 71 per cent of manufactures, occupies only about 11 per cent of the land area of the United States.

The South, east of the Mississippi River, has about 25 per cent of the population and 14 per cent of the manufactures in an area roughly 22 per cent of the nation, and the vast open country west of the Mississippi contains more than 66 per cent of the land area, but only 25 per cent of the population and 16 per cent of the manufactures.

There would be nothing significant in these figures if our business organization ran smoothly. However, the basic cause for industrial decentralization is the fact that there is too much productive capacity and that there are too many manufacturers each trying to sell the whole nation at once, coupled with a less rapidly increasing population and consumer demand (to say nothing of financial parasites and uncontrolled machine fecundity displacing employees), and this has led to such intensive competition for customers that most industries can no longer compete successfully for customers that are too far away nor produce efficiently in factories in congested centers. The average manufacturer today and from now on, therefore, realizes that the fundamentals of successful manufacture must be as follows:

Distribution: Knowing customers' needs, and changing products to suit; quick and cheap deliveries to customers; personal contacts with customers, and therefore customer loyalty.

Production: Employee and shop teamwork, high efficiency per man; basic low costs in land, plant, taxes, transportation facilities, and living and amusement costs for workers.

So intense is the competition, since production overtook consumption in 1925, that every one of these fundamentals is necessary for every manufacturer except those with highly superior or patented product or management and those concerns, such as newsprint, whose location is determined purely by nearby materials. These fundamentals, it is clearly seen, can be obtained only by plant locations in cities that are not congested and where labor conditions and costs are favorable; and in locations as near to the chief markets as possible. To be near customers is to have the great advantage today. There is a limit to selling and shipping radius from the plant beyond which customers are lost track of, deliveries are slow or costly, and more favorably located competitors have the inside track. In short, the strong tendency now is medium-size or small plants each covering a surrounding market region of from 100 to 1000 miles radius, depending on the line of industry, the competition geographically, the transportation facilities, etc., with a rough average of 500 miles radius.

The overdevelopment and intense competition in every line of industry will keep on increasing and will force the average manufacturer to concentrate on the market within truck or fast rail delivery of his plant, to know that market well, and to hold on to it. Steady sales, and full-time operation of a smaller plant, with capital, overhead, and expense adjusted in proportion, will enable him to make more economies, maintain full-time employment at higher wages, give more quality at lower prices, and enjoy more stable profits, than the present highly fluctuating sales volume has ever given him a chance to do.

JOHN N. JITKOW.[20] With the difficulties of the present times it has become quite fashionable to lay all blame at the door of the concentration of industry. And the proposed remedy is largely very simple: the evil lies in concentration; therefore let us deconcentrate or dissolve the concentration, and everything will be all right. Some advisers proposed to create a substantia tariff wall and to return to the status at about the time of the Civil War; others would pattern after the balanced state of industry and agriculture in France; and, finally, there are those with whom the author agrees, who are satisfied to rely upon a general dissolution of concentration.

It makes no difference how far the proposed regressive march has to go, for it is quite obvious that the advisers do not clearly understand the significance and role of the normal industrialization process, the correlation of the present-day culture with concentrated industry.

The industrialization process has been developed by all nations in similar, parallel lines—not all at the same time, but the difference being only in the tempo and rate of industrialization.

The true independent measure of industrialization can be derived by superimposing two forms of industry: one which has produced goods for immediate consumption; the other, capital or productive goods, which are now available for the future. The first embraces foodstuffs, textiles, the clothing and leather industries; the last, iron and steel, the production of machinery, and different metallic goods, including the transportation media and the chemical industry.

In every industrialization process everywhere there existed the consumption industries at the beginning, and only when capital, credit institutions, and trained workmanship attained sufficient size and strength did the capital goods industries appear on the national stage. The output of the consumption goods industries at first was 100 per cent of the total; then with the increase of the capital goods industries, there came a time when 50 per cent was allotted to the consumption and 50 per cent to the capital goods industries. This moment in the United States fell in 1909, in Sweden in 1914, and in Belgium in 1927. If we present in ratio form the output of both types of industries, we shall secure the most significant characteristic for a given moment and a given nation.

If we divide these capital/consumption ratios in the four groups[21] of: higher than 1/2.8, of 1/2.79 to 1/1.7, of 1/1.69 to 1/1, and of less than 1/1, we shall have for corresponding periods: the industrialization start, maturity, building of heavy industries, highest concentration.

Every period as an independent variable has many dependent functional values: The corresponding increase of wealth of the nations, the percentage of the working and town population to the total, and, what is most important, the situation of organized labor. In the first period we see the beginning efforts to organize local trade unions; in the second, organization on a national basis; in the third, efforts to amalgamate; and in the fourth, organized labor not yet satisfactorily expressing itself. For the most part, most concentrated capital goods industries actually are not unionized. Craft unionism supported mainly by the American Federation of Labor does not satisfy either employer or employee, nor is it adjusted to the social and economic order of the country, as opposed to the structure of highly concentrated industries. The automotive industry is the best example of this.

Without any reference as to what route the economic evolution reflected in the coming legislation will take, it is clear that a soundly organized labor movement, normally developed and corresponding to the concentrated form of industry, will greatly help to induce any possible kinds of changes intelligently and smoothly.

Observing the relation of the industrial and functional factors corresponding to each phase of industrialization, we see nearly the same picture in every country; this correlation is not the consequence of occasional causes, but only of the play of economic forces expressed on the stage of industrialization. In his present solution, the author, like most interpreters of our present-day difficulties, has mixed up the original cause (the coincidence of cyclical low point and the war aftermath[22]) with concentration which has nothing abnormal about it and on which the whole present culture is exclusively based. To deconcentrate industry and the whole social and economic structure is more impossible than to bring back the flow of a river.

One point in the paper is of great value—the statement that "the engineer must become economic minded if he is to play his part well and serve society as it should be served." In this categoric "must" we see the desire to bring together two most important branches of modern life, engineering and economics. There lies the center of gravity of the future order or disorder.

Another man, a great engineer and scientist, the last winner of the Nobel prize, Dr. Langmuir, gives more precisely the reason for our difficulties. It does not lie in concentration, but simply in the fact that "applications of physical sciences have gone ahead faster than the development of economic sciences. Our economic system does not enable us to profit efficiently from the gains contributed to industry by the discoveries and inventions of science." This is the actual difficulty. The physical and engineering sciences are already in an established maturity, while economic sciences are still in their infancy. In the nineteenth century we saw a most efficient growth of the first and an abnormal development of the second. Physical and engineering sciences took a decidedly quantitative-experimental course, while the parallel development of economics lagged under the strong influence of ethics and the fluctuations of philosophic theories, occupied with qualitative determinations, with only rare quantitative excursions in the field of statistics. Since the example of Adam Smith, whoi ntroduced a "homo oeconomicus," there have been only abstract concepts such as "owner," "employer," "worker," and the like; very seldom actual figures and relations. Any marked change can be observed only after the words of A. Marshall, who, twenty-five years ago, in the Royal Economics Society, said that "qualitative analysis has done the greater part of the work in economics, and the higher and more difficult task of quantitative analysis must wait upon the slow growth of thorough, realistic statistics."

The task has not been an easy one, but such men as Prof. W. Mitchell have greatly advanced the behavioristic, quantitative approach in the economic sciences, which produced general and irrevocable change in some of the most important factors of legislation of all the civilized world. But the gap between economics and engineering is still a great one, and there, and only there, are located all of our present troubles.

In all false reasoning there always exists a trick, a jump in logical developments of argumentation, usually not seen in perspective at the first glance. This leap one may find easily in the author's thinking. He sees "light and happiness" in the dissolving of industrial concentration executed in the form of many smaller plants, the location of which "will be chosen with a scientific regard for the factor of distribution." He does not open the secret of "scientific regard," explaining only that this will be done in connection with "scientific marketing." In submitting the program of dissolution and organization of the smaller "scientific"

[20] Mechanical Engineer, New York, N. Y.

[21] By such division we may easily find the real location of the much-praised balanced French industry. Its present situation, with the ratio 1/1.5, corresponds to the American of 1866.

[22] Which in the more primitive state of post-Napoleonic wars desynchronized and threw out of rhythm the economic system for more than 20 years.

units, it is understood if not expressed that the dissected industry has to have static stability.

This presumption is a major hiatus in the author's reasoning. Life is motion, and industry is its most dynamic expression. Life and industry are not a pond, but a real, flowing river, with necessary adaptations of form, speed, temperature, amount of flow. The large city with its resources and reserves gives opportunities for permanent reconstruction, for competition of ideas, and a change of production methods. Most of the inventions that have become the closest attribute of our present-day life and of our high standard of living, even the human material vividly expressed in the type of Edison, Langmuir, and Ford himself, are the direct product of concentration.

If we will analyze the relation of the proposed dissection of the various types of industries, we may see that the consumption goods industries could be dissolved according to the author's plan because—

1 The methods of production there do not undergo such revolutionary changes as in the capital goods industries
2 They are not the attribute of exclusively large units (if we take the European example, we see that most of the consumption goods industries exist on a most decentralized basis)
3 There is the comparative stability of distribution.

As to the capital goods industries, they are not able to exist or even to survive in dissected form.

The normal way lies not in the dissolution of capital goods industries, but in higher concentration. "More machines and increased application of science are inevitable and highly desirable, provided the set-up is such as to enable all to share the benefits," says Langmuir.

While the engineering side gives us a complete account of what we have and what we can expect, the economic is comparatively obscure, undermined, and befogged. The dissolution of industry, even in bringing much lower efficiency and higher cost of production, will never solve the problem. The factor of greatest confusion and complexity in our situation lies exclusively in oversupply of human material and commodities.

Of the two oversupplies, the human is of greatest concern and is closely connected to the possibility of grave consequences. There is no doubt that the workers will benefit by the bettering of his standard of living by the introduction of gardens and the like. The occasional application of the Ford plan ("one foot on the soil and one foot planted on industry") can be very beneficial, but there rises a very serious question: To what extent can this measure be practically and not theoretically introduced on a large scale? It is unreasonable to expect to find the solution of our problems in the half industrial worker, half farmer. It can be a local palliative, but not the general cure.

Author's Closure

The author is indebted to those who have brought out in their discussion the various phases and aspects of the subject that could not be included in a paper of this character, primarily by reason of space restrictions, and also for calling attention to matters which the author overlooked. He is indebted to Dean Kimball for bringing out so clearly the operation of the law of diminishing returns; to Mr. Heckman for pointing out the operation of the change in emphasis, the relative importance and the realignment of the primary factors and forces influencing industrial-plant location—he is quite right in calling attention to the fact that as a practical matter it is difficult to clearly distinguish at all times between economic and sociologic forces; to Mr. Giele for pointing to the greater economic security of the workers that has been developed by several industries in Lebanon County, Pennsylvania; to Mr. Hopf for calling attention to the necessity for a proper balance between the desire for profit and the welfare of the employed; to Mr. Taube for rightly calling attention to the fact that we do not now have at our command the necessary basic data to forecast what the results might be if a large-scale redistribution of industrial units was to take place, and furthermore that the dissolving of concentrated industries of itself will or can supplant the effects of sound policies and righteous dealing on the part of management; to Mr. Piquet for pointing out that sound marketing conditions will in the future be the predominant force in industrial-plant location; to Mr. Jitkow for emphasizing the fundamental economic differences between the capital-goods and the consumptive-goods industries, and that the latter are probably more readily amenable to forces of redistribution than the former.

The author has been credited with advancing a plan for the dissolution of concentrated industries. Such is not the case. He has endeavored to collect and analyze much of the available material, so as to point out the trends and the forces at work; and he hopes that, with this paper and discussion as a base, a sound literature on the subject will be built up so that management can compare their individual situations with the general trend and thereby keep in step and in line with the times.

MAN-55-4

Planning and Scheduling

By WALTER N. POLAKOV,[1] NEW YORK, N. Y.

The process of planning presupposes an aim to be attained, and therefore it is a purposeful action. It may or may not have a clearly conceived means for this achievement or a clearly determined order of procedure. These two elements, the means or facilities for the achievement of the aim and the order of their utilization, determine the quality of planning. The author analyzes the requirements, cites the work of Taylor and of Gantt, lists the preferred methods in use, and reaches definite conclusions, summing up with: Planning is a reversible process tending to reduce the element of random.

THE process of planning necessarily presupposes an aim to be attained; therefore it is a purposeful action. But it may or may not have a clearly conceived means for the achievement of the aim, and it may or may not have a clearly determined order of procedure. These two elements, the means or facilities for the achievement of an aim and the order of their utilization, determine the quality of planning.

If the means or facilities for securing the desired result are undetermined and the order of procedure is not defined, the probability of its attainment is extremely remote, depending on the chance offered by the uncontrolled circumstances.

If the means for securing the desired results are determined, but the order of their exercise is indefinite—i.e., left to chance and not subject to the influence of planning—the degree of probability of securing the desired results is higher.

If the means for securing the desired results are determined and the order in which these means are brought into play are likewise determined, then the probability of attainment is very high.

If the order of events is determined as to the place and time (sequence), but the selection of means is left indeterminate, the obtaining of the desired results depends upon a chance offering the opportune means.

If the order is indeterminate, but the necessary and sufficient means or facilities for securing the desired results are present, the successful outcome of such a planning is very improbable

If the order of procedure is determined as to the place and time (sequence), but the means or facilities are only partly determined—i.e., if the means selected are necessary but not sufficient, or one or more elements are beyond our control—the degree of probability of attaining the aim depends upon the factors not fully under control.

Thus the perfection of a plan increases with the decrease of variables or indeterminate factors, and analysis of sufficient conditions is the essential requirement of planning. Since, however, in the complexity of life, to foresee all possible influential variables is practically impossible, most planning is typified by cases wherein either the order of procedure or some of the means are left either to the uncontrollable economic forces or to the choice of an executive. Hence most of the industrial planning is subject to the readjustments during the execution, and therefore must necessarily be augmented by continuous and graphic records of progress in order to observe the deviations and decide upon the corrective actions.

This interdependence of planning and executive work is of extreme importance in practical life. The full appreciation of this fact will establish a proper relation between a plan and the executive action. Therefore the technique of planning and the method of presenting data for the guidance of the executive actions should form a united whole in any system of management. The process of industrial, or more specifically production management is therefore neither merely planning of industrial activities nor merely execution of plans, but it is a continuous adaptation of a plan to the variable circumstances and influencing the circumstances to meet the requirements of the plan.

Hence, planning of the means or facilities for efficient production alone is inadequate for any degree of certainty in management. For instance, a well-planned maintenance and the carefully devised "trademarked" systems like "Manit," "Bedaux," etc. could produce a measure of good only if the order of work is well taken care of either by the nature of the process or by the supplementary efforts of the management.

Likewise, if the planning be limited to the establishment only of the order of procedure, such as may be found in conveyor-type assembly shops or continuous operations or elaborate semi-mechanical and semi-clerical planning boards, there could be no assurance of efficient execution if the means or facilities are receiving inadequate or spasmodic attention instead of being subject to a well-planned care.

Taylor's earliest description[2] of planning enumerates 17 leading functions. From the perusal of his list it is apparent that the stress was laid on the conditions or facilities for a planned production, while the order of the planned procedure assumed a secondary position. Of all these 17 "leading functions," only one directly refers to time of delivery. The emphasis was placed on time studies on the assumption that, if every piece of work is done in a specified time, the whole will be done as expeditiously as possible. That this is not the case is evident from the consideration that some parts may be manufactured rapidly, but in larger or smaller quantities than others, thus producing an unbalanced flow of parts into the assembly.

As far back as 1888, Gantt realized the paramount importance of the element of order in the planning, and in the steel-casting

[1] Consulting Management Engineer. Mem. A.S.M.E. Walter N. Polakov received his engineering education in Koenigliche Technische Hochschule at Dresden, and since 1906 practiced the engineering profession with Harrington Emerson, at American Locomotive Company, and for years with H. L. Gantt. During 1909-1910 was expert consulting engineer for the Board of Estimate, New York City. He was associated with Day & Zimmerman on introduction of scientific management at Penn Central Light and Power Co.; was superintendent of Power, New Haven Railroad, until the end of 1915. During the war was power engineer, U. S. Shipping Board Emergency Fleet Corporation, and on other assignments. Incorporated in 1919 as Walter N. Polakov & Co., serving as management consultants. Author of "Mastering Power Production," "Foremanship," "Man and His Affairs," "Power Plant Management," and over a hundred professional papers and magazine articles.

Presented at the Informal Management Conference, Metropolitan Section, sponsored by the Management Division of The American Society of Mechanical Engineers, New York, N. Y., January 6, 1932.

Note: Statements and opinions advanced in papers are to be considered as individual expressions of their authors, and not those of the Society.

[2] F. W. Taylor, "Shop Management," p. 111.

department of the Midvale Steel Company he developed the graphic daily balance, which he described years later as applied by him to the Schenectady shops of the American Locomotive Works.[3]

Time keeping and timing the workman had been done long before the industrial era. As men were paid by the day, it was important to keep track of the time they worked and of the amount of work done.

With the speeding up of our industrial tempo, the time for completion of an order began to play a dominating part in the process of planning. In the past a shop order usually stated only what was to be done, but Gantt realized that under the changed economic conditions the final date alone would not suffice. Planning had therefore to include not only the means of doing the work, but also the time order (sequence) of doing it, thus:

1 What is to be done
2 When it is to be done
3 Where it is to be done
4 How it is to be done
5 How long each detail may take.

To inaugurate such a system, it was necessary to have a running balance of finished parts and to follow daily the progress of parts in the course of manufacture as they passed through the shop. Such "planning as a whole" has a structure of order in time. The functions of a manufacturing (planning) office, according to Gantt, may be enumerated, in general, as follows:

Handling material: (1) Purchase of material, (2) custody of materials and stores, (3) what shall be done to the material (drawing and specifications), (4) when it shall be done (schedules), (5) movement of the material through the works (routes), (6) care of finished product.

Handling men: (7) How the operations shall be performed on the material (use of equipment, instructions to workmen), (8) what compensation shall be awarded for the work.

Since it is obvious that the last two functions cannot be properly performed unless functions (4) and (5) are well planned and properly executed, the attention of planning must center around the order of progress in time (schedules) and space (routes).

The order in which the various operations are to be performed being determined as a part of planning, the next important function is to see whether the actual progress of work follows the route on time. The early device was Gantt's graphical daily balance in manufacture. It consists of a sheet of paper with vertical columns listing the parts to be manufactured and the operations to be performed on each. The horizontal lines represent the consecutive dates. We thus have jobs on abscissa and time on ordinate. In each column are entered the number of pieces finished daily and a cumulative number of pieces finished to date. The date on which all parts on order are to be finished is underscored beforehand in red, and thus offers a visual warning. If the numbers continue to appear below the line, it indicates that the production is behind the schedule.

Gantt later devised what is now called the "Gantt chart." This new device for planning considers time, space, and matter as "an event" and uses one scale indicating at once by a single line the sequence of operations (order), the quantity of product, and the time of separate operations as well as the dated completion of an order. The construction of the Gantt chart is well known; its typical features are:

1 The multiple scale, such as: Time and matter, time and energy, time and space, time and ratios of any kind, etc.

2 Comparison of the preplanned task with the record of its performance.

[3] "A Graphical Daily Balance in Manufacture," by H. L. Gantt, Trans. A.S.M.E., 1903, vol. 24, p. 1322.

Unless both of these features are incorporated in the chart, it is a fallacy to term it a Gantt chart.

Planning of order is of little use unless it is organically tied with the records of performance. Once this is accomplished, however, the process of planning ceases to be a theoretical problem which, once solved, becomes a law unconcerned with its enforcement and having no part in the judgment of transgressions. To the contrary, it becomes a basis for judgment and it determines corrective actions.

Planning, as a whole, involves the responsibility for the fulfilment of the plans. This fundamental principle of management makes planning a dynamic process instead of a static set of demands. To make the planning process a dynamic force and an active tool of management, there must be an inseparable interconnection established between the task set by a plan and the record of the progress made and the handicaps encountered, as shown by charts.

The mechanism of this interconnection, as offered by the modified method of chart analysis, permits a continuous (daily or for every shift) control of the progress of the work and the correction of troubles. The simplest form of this mechanism consists of a progress chart on an output-time scale, supplemented by man-record and machine-record charts. As the short bars lagging behind the date of observation indicate delays in the performance and the causes of these shortcomings, these charts afford the opportunity to readjust the means or rearrange the order in time to avoid any serious disruption of plans.

In the typical industrial establishments the planning of production must coordinate and plan the following means of getting work done:

1 Material procurement
2 Storeroom service (raw, semi-finished stock)
3 Toolroom service (tools, jigs, templets, dies)
4 Maintenance department (equipments and building)
5 Power department
6 Safety, sanitation, welfare
7 Employment and personnel department
8 Training department (job studies, tasks, instructions)
9 Dispatching and transportation
10 Payroll and cost keeping
11 Engineering department (drawings, specifications)
12 Schedules (sequence of processes and operations, routes, process charts, time allotment)
13 Shipping
14 Record and chart keeping.

These means, in order to be of full value to production, should be used at a definite time, in a definite place, and in definite quantities. The establishment of an order in which these means should be used to obtain the optimum results is the function of planning proper.

It is obvious that the planning may be started before all the means are correctly organized and exhaustively studied. Indeed, until the planning of order is installed, there is no certainty as to which of these functions impede production. On the other hand, some planning as to sequence of operations, means required, time needed, etc. can be started on the basis of the available common knowledge and past experiences.

It is not disputed that job standardization and various forms of incentive payment have their place in the practice of management. Yet these means do not constitute a system of management, and under no condition should they be installed before planning of the work order is installed and is functioning well. If, however, the order of management installation is reversed and the tasks are set or piece rates are fixed before the planning of the work order and Gantt charts have their effect, then it will soon

become necessary to revise the tasks and methods of payment again. Besides the duplication of expense, such a topsy-turvy procedure is likely to produce demoralization and lead to the restriction of work output by keeping the day pay within the old limits.

In order to find out which of the means of production are improperly utilized or poorly functioning, it is necessary to map out the sequence and the order of procedure in time, and then to enter on this map daily the course covered. In this manner the attention of an executive is immediately fixed to those elements which create delay or cause some trouble. The progress chart will indicate whether the parts needed are delivered on time and in required quantities, and if some deliveries are behind, the symbols will indicate the reason why and lead to the correction of it. The machine-record chart will show whether the equipment is properly utilized, and if not, why not. Both these charts will locate the more serious troubles and point out the remedies. Such a study will picture the activities of the management in making the proper use of the facilities and means at its disposal. Later on a third chart, a man-record chart, should be started to bring within the scope of vision of each workman and his foreman the troubles that handicap his work and thus finally "remove the obstacles which confront the workman."

When at least three basic forms of charts are kept for some time, and the most important weaknesses or functional disorders of an organization are thus disclosed, it is possible to install a more inclusive planning. While the elements subject to planning are essentially the same in every type of industrial establishment, the principles underlying the planning functions are independent from the nature of the product or the scope of production. In every case, in order to have the product ready in time, production planning must see that:

(*a*) Needed material and supplies are available when wanted, where wanted, and in quantities required
(*b*) Needed equipment (machines, tools, power, transportation) is available in the best working conditions and fully utilized
(*c*) Needed men are available and provided with necessary instructions and rates. Then, according to the specifications and sequence of technological processes
(*d*) Schedules of work for men and machines and movement of material are worked out.

The nature of the product and the quantity in which it is produced will determine the character of planning organization. There are two types of industrial enterprises:

1 Manufacturing one or few types of product in large quantities (mass production)
2 Manufacturing on individual specifications in relatively small quantities (production on order).

The typical instances of the first type of manufacturing establishments would be textile or paper mills, large automobile plants, sugar mills, etc. The typical instances of the second type of manufacturing establishments would be a locomotive shop, a printing plant, tailoring establishments, etc.

The organization of a planning department in an establishment for mass production of a single product will be concerned chiefly with the control of materials and men. On the other hand, the organization of a planning department of a jobbing or individual-order plant will be chiefly concerned with routing and dispatching of separate orders and planning of the load for equipment, in addition to the control of supply of material and labor. This shifting of the emphasis either on means or on order will determine the structure of the planning office and the divisions of functions.

Evidently a large number of manufacturing establishments will not fall definitely into either one of these two classes, as for instance a machine-tool-building plant manufacturing a standard type of tool as well as taking orders on special machinery, or a garment factory manufacturing only two types of overalls, etc. In other words, of the two features of a manufacturing establishment, volume and variety, dominating importance may be shifted, presenting four types:

1 Large volume production of a single article
2 Large volume production of a variety of articles
3 Small volume production of a single article
4 Small volume production of a variety of articles.

Correspondingly, the structure of planning will tend to give attention to the planning of the means with increased volume and to the planning of the order with increased variety of products. In an extreme case of mass production of a single type and size article, the planning of an order will become automatic.

A mechanism of preliminary planning of an order may be clearly exemplified in a case of a machine shop manufacturing machine tools in series of widely different types and designs. In order to reduce to a possible minimum the variety of elements entering the finished machine, the parts, such as gears, cranks, pumps, flexible couplings, bearings, etc., were standardized so that they may be used for any type or size of machines. Other parts were made in as few as possible "normal" designs to fit likewise most of the machines. A designer, upon receipt of an order, works out a set of detailed working drawings, incorporating nothing but normal and standard parts of suitable dimensions, and designing individually only such special parts as probably cast frame or base.

Next, the production superintendent, together with the designer and in consultation with the various foremen, works out the sequence of processing as to planning, drilling, milling, polishing, etc., designating the class of factory equipment best fitted for the work and indicating also the possible substitute machines in case no machines of the preferred class are available at the time in the shops. The list of "normal" parts, a set of working drawings, and the manufacturing schedule with the classes of machines are then referred to the planning department.

The material-planning clerk or the balance-of-stores clerk compiles the cards for each individual part to be manufactured, specifying the following data, on a material card of a suitable design, for each element:

1 Part number and name
2 Stores symbol
3 Grade of material
4 Size
5 Weight per piece
6 Requirement (number of pieces, weight)
7 Balance on hand
8 Amount to be ordered
9 Expected delivery (name of supplier, quantity ordered, date of delivery)
10 Note surplus or deficiency for order.

From these material cards a summary of "material wanted" is prepared, tabulating each kind of material needed for the order, and is sent in triplicate to the purchasing agent and to the balance-of-stores clerk in the manufacturing office, so that they can make the necessary arrangements to avoid shortage. The third copy goes to the production superintendent or foreman.

The machine-load clerk at the same time prepares the cards for each part necessary for the order from the data furnished by the production superintendent and engineering department, showing on each card:

1 Part's number or symbol
2 Numbers of operations, consecutively
3 Manufacturing department
4 Shop
5 Numbers of machines to be used
6 Time allowed on each machine
7 Total time needed (all machines or men)
8 Notes (substitute machine or ready parts in store).

The personnel clerk, upon receipt of these cards, makes a summary of labor hours needed for the different classes of work, estimates the labor cost, and makes the necessary reports as to adequacy, excess, or shortage of the present force on the payroll.

The cost estimator, upon receipt of both material cards and machine cards, works out the unit cost from them for each part in every department. Thus the estimate, for instance, for part 74 (100 needed) will be:

Material	$0.03	$ 3.00
Labor, Dept. 4	0.01	1.00
Machine, Dept. 4	0.03	3.00
Labor, Dept. 6	0.025	2.50
Machine, Dept. 6	0.02	2.00
Total	0.115	$11.50

(Stores, $3.00; Dept. 4, $4.00; Dept. 6, $4.50.)

Finally, the manufacturing office, which is the planning department proper, receives the worked-out preliminary requirements for materials, machines, and men needed for the order (cards and summaries), together with the form order, drawings, and specifications. The first duty, then, is to consult the load chart and to reserve the time for the use of the machines needed. The date of delivery to the assembly floor is thus determined, and from it the delivery date is fixed. If it is a rush job and the date thus determined is later than wanted, the departmental layout charts or machine-record charts are consulted, and, in cooperation with foremen, readjustments are made to meet the promised date. Once the final date of shipment is thus fixed, it is entered on the progress chart by placing a closing bracket two days ahead of the promised shipment, allowing time for the final inspection, testing, and boxing.

Inasmuch as the assembly and erection of machines is made on the schedule of so many units per day, the finished parts are drawn by the assembly department from the finished-parts store. This is the most vital point for constant supervision, and the input-output chart is kept indicating the daily receipt of finished parts in the store and their issue to the assembly, seeing that a safe balance is always on hand.

It was found that detail planning and despatching can be best made, not in the central planning office, but in the shops by their foremen. Every afternoon the foreman ascertains whether new orders were received and what work is ahead. Consulting his machine record chart and layout chart, he determines what work he can do tomorrow and, accordingly, prepares the "daily order of work," listing all the work he is prepared to do opposite each machine in the shop, thus:

Machine number
Order number
Description of part
Tools, dies, templets, etc.
Operation
Quantity (or weight)
Start
Finish
Running
Cause of delay
Postponement.

Upon approval by the superintendent of production of his plan to run the machines as indicated, the foreman passes the "order of work" to the respective dispatchers in his shop, who accordingly make the necessary entries on their layout charts, and also secure material and assign men. The stores-issue slips and time cards are prepared beforehand by a clerk in the foreman's office.

The shop dispatcher, having his desk and bins located centrally in the shop, continually observes whether the work issued to the men is returned within the time allotted as marked on the layout chart, and if not, he makes inquiries as to the reason why, enters the symbol on the chart, and refers the matter to the foreman; then he extends the time for the completion of the job if it does not interfere with another job previously scheduled, and if it does interfere, he consults the foreman. When the work is completed, the dispatcher issues the next job, stamps the time card, and makes the necessary entries on the layout chart.

Toward the end of the shift, the foreman examines the layout charts and notes the progress made and the work that is behind the schedule. This enables him to prepare the daily work order for the next day with the full knowledge of the available facilities. If some of the work cannot be done as planned and the foreman is unable to remedy the trouble himself, he notifies the superintendent of production by sending a "report of delayed work," requesting his executive action.

In different shops it will be found that the layout charts are to be made on different bases. For example, in a machine shop or forge shop the work will be laid out for each machine, while in a plating department it will be preferable to lay out the work by orders, since each part must pass through several operations such as soldering, plating, relieving, polishing, etc. In every case, however, the aim of shop dispatching is to schedule the flow of work so that:

1 Every machine has work assigned to it
2 Every machine is provided with materials and tools
3 Every machine is provided with an operator
4 Every order is started on time
5 Every order is finished on time
6 Every part is moved from operation to operation
7 Every part can be located at any time
8 Every defect or delay is accounted for
9 Time taken is accounted for
10 Time lost is accounted for.

The proper use of the layout charts, based on the foreman's daily order of work, is the principal guide for this work.

In this manner planning is no longer centered in the main office, divorced from the shops, but permeates the organization. The central planning department does not presume to know as intimately as the foreman does all the minute conditions in the shop, but gives the foreman authority (within the general requirements) to do his own planning and makes him assume the full responsibility for the work over which he has control, instead of laying the blame on the main office for asking him to do impossible things. The workers, likewise, are given an opportunity to do the planning within their scope of competence, aided by the information contained in the instruction cards and limited by the time allowed. The use of the man-record charts both stimulates the efforts to excel and reflects the ability to plan the use of the means and facilities under their command. They also reflect the efficiency of the foreman in planning the sequence and conditions of work for his men and removing the obstacles that are in their way.

Budgeting is not a substitute for planning, but is an interpretation in financial terms of a plan already prepared. When the manufacturing schedules are laid out and the required capital investment, obsolescence reserve, and fixed charges are deter-

mined, the operating, maintenance, and administrative expenses can readily be expressed in monetary terms and balanced with the revenues anticipated for the given output and time taken as a frame of reference. The budget progress chart admits the same technique of graphic presentation and control as is established for the production control. Operating control of budget may be laid out on a departmental basis if a single product is manufactured or on the unit of product basis if a variety of articles are planned for production.

Similarly, national economic planning depends on the same principles and technique. It begins with an estimate of the total bulk of consumption anticipated for a period under consideration. Then the stocks are balanced to the period needed for the new product to reach the market, thus establishing the beginning of new deliveries to consumers. Production volume is then allotted among the manufacturing establishments, considering the centers of consumption, material sources, and productive capacities of the respective plants, and readjusted, giving preference to the more efficient productive units. Budgeting, coordination with outer sources of supply and export, building up of reserves, and control of performance are then handled by a graphic method on the basis of weekly returns.

Planning and scheduling conceived along these general lines presents not only a logical structure, tying into one harmonious whole (*a*) mapping the procedure, (*b*) recording the progress, and (*c*) executive direction of the deviating forces, but also a structure that functionally corresponds with our nervous system. In the old conception of planning: "All possible brain work should be removed from the shop and centered in the planning or laying-out department, leaving for the foremen and gang bosses work strictly executive in its nature. Their duties should be to see that the operations planned and directed from the planning room are promptly carried out in the shops."[4] This creates an undesirable domination of a static planning room over the dynamic shops.

In the human nervous system it is found that the central part of the brain (thalamus) has a direct connection with the sense organs and locomotion, while the "gray matter" of our brains (cortex) has no direct contact with the outside world, but receives all the impulses through the thalamus. Hence, these are well-coordinated activities of a normal person.[5] In our conception of planning there is structurally a similar organization; the dynamics of production through the records and charts (sense organs) has a direct contact with the lower centers of planning, the higher centers of planning receive the informations and then coordinate and influence the executive reactions. There is no gap between the "thinking" and "doing without thinking," hence the organization works smoothly, responds precisely, and does not create dissatisfaction or resentment against the "task masters."

Conclusions

(*a*) Planning is a process of determing the structural order of actions in a four-dimensional space (time-space).

(*b*) The process of planning aims to specify the conditions that are necessary and sufficient for performing the desired task.

(*c*) The analysis of conditions differentiates between "facilities" and "order."

(*d*) An established "order" determines the necessary and sufficient conditions for the efficient use of "facilities."

(*e*) The established "facilities" do not determine the "order" of procedure, neither are they sufficient for securing the desired result.

(*f*) An analysis of the elements of planning depends upon continuous information as to the progress of the previous plans.

(*g*) The instrument of analysis and planning is a chart which places the elements in order structurally corresponding to the reality (establishing what should be and plotting and measuring the deviations of what is, similar to the navigator's map that pictures the course to follow and records the progress and deviations made).

(*h*) Therefore, planning is a reversible process tending to reduce the element of random.

Management Policies and Practice in a Continuous-Production Gray-Iron Foundry

By W. G. REICHERT,[1] ELIZABETHPORT, N. J.

In a continuous-production gray-iron foundry with a capacity of 250 tons daily, chiefly making small castings, the management policies and practice have been directed toward obtaining maximum results by the continuous molding-pouring method with the minimum expenditure of time and effort. The operation of this continuous foundry is described in detail, through all the processes from handling the raw materials to the final inspection of the product.

IT CAN BE considered an axiom that the success of an industrial enterprise depends on the coordination of its management, mechanical, and technical branches, so that maximum results are obtained with a minimum expenditure of time and physical effort. There are few branches of industry in which this is more evident than in the foundry, where the repeated handling of the materials and the product forms the major cost of production. It is the purpose of this paper to discuss how a foundry with a maximum capacity of 250 tons daily, engaged chiefly in the manufacture of small castings, has attempted to solve the problem by the continuous molding-pouring method and to mention some of the details that have been found necessary to assure the success of that method.

DESCRIPTION OF THE FOUNDRY

In order to understand clearly the management policies employed in this foundry, it will be necessary, first, to describe briefly the foundry itself and its operation, and later to coordinate this with the management practice. The foundry as a whole is divided into four departments: the jobbing foundry, where castings for machine tools and equipment used throughout the factory are made, the hand-molding foundry, the non-ferrous foundry, and the continuous foundry. This latter foundry is the one that will principally be discussed, and the one where approximately 85 per cent of the total tonnage is cast.

[1] Engineer, Singer Manufacturing Company. Mem. A.S.M.E. Mr. Reichert was graduated from the Polytechnic Institute of Brooklyn with the degree of B.S. in Chemical Engineering and has been employed with the Singer Company since 1918. He has been particularly interested in the metallurgy and metallography of the ferrous and non-ferrous metals, and a major portion of his work has been in foundry methods of control, development, and manufacture. He is chairman of the Grading Committee and Shop Operation Course Committee and a member of the Joint Committee on Molding Sand Research and the Program and Papers Committee of the American Foundrymen's Association. He is the author of numerous papers presented before the American Foundrymen's Association on development and research for the improvement of cast-iron founding and has also devered lectures on foundry developments.

Contributed by the Management and Materials Handling Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS and presented at the "Three-M" (Management, Materials, Maintenance) Congress held in Detroit, Mich., May 4 and 5, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The melting equipment consists of two cupolas of a capacity of 250 tons each, two of a capacity of 180 tons, and two of 90 tons. One cupola of the size necessary for the tonnage required is used each day, the second one of the same size being prepared for operation on the following day. Each cupola is served by two charging machines located opposite each other, and the coke, pig iron, scrap, and sprues are charged in the order indicated throughout the working day.

The continuous foundry is a concrete structure, designed for this specific purpose and for the machinery to be installed, and is conveniently located to receive raw materials by rail or boat. The building may be considered as two abutting buildings, which for the purpose of identification will be called the east section and the west section. The east section is three stories high, while the west is four, although the ground floor and the upper floor of each section are on the same level. The molding and shaking out of the castings, as well as the sand preparation, are performed in the east section, while the cleaning, filing, grinding, and polishing are accomplished in the west section. In a northerly southerly direction the east section may be considered as divided into six sections designed for installation of six independent mold-conveying and metal-pouring units. Five of these units have been installed, and the framework is in place for the sixth, should it be required. Each unit is complete in itself and consists of a battery of eight hydraulic-molding presses, with its own mold-conveying, sand-preparation, and distributing machinery.

The molding is done on the ground floor, the mold is conveyed to the pouring station, also on the ground floor, and is then conveyed to the west end of the upper third floor of the east section, where it is shaken out, the empty flasks being replaced on the conveyor and returned to the molding floor.

HANDLING RAW MATERIALS

Raw materials are received by boat or rail. Cranes, equipped with magnets and clamshell buckets, unload all incoming material, transferring the pig iron, scrap, coke, and limestone to a designated section of the raw-material yard, while the sand is delivered to inside storage bins. The raw-material yard is exceptionally flexible, being well supplied with industrial tracks in order to facilitate the loading of the materials as quickly as possible and with a minimum amount of handling.

Definite weights of coke and iron are made up on the ground floor and are delivered by industrial charging cars to the charging platform by elevator. Sprues and gates are continually being returned from the shake-out stations of the continuous foundry via chutes and conveyors to the charging cars, and later weighed and delivered to the charging platform, which is located on the same floor level. In this way the hot sprues are returned to the cupola less than one hour after the molten iron has been poured.

The blower room is located on a mezzanine floor adjacent to the cupolas and between the charging floor and the foundry floor proper.

For continuous operation it is important that the metal be delivered regularly to the mechanical systems. The molten iron, in 500-lb ladles, is delivered to each molding unit by monorail cranes that pass directly in front of the cupola, delivering continuously throughout the day. The metal is then emptied into 50-lb

hand ladles, and the molds are poured, while the operator stands on a secondary conveyor synchronized to the speed of the mold-conveyor unit.

The slag from the cupola is granulated in order to handle it effectively. Water under pressure granulates the slag as it flows from the slag spout, carrying it along cast-iron ducts leading to a reservoir. At the end of each operating day a clamshell bucket removes the slag to open-top cars.

Sand Preparation and Distribution

The preparation of sand for 20,000 molds each day is an important item, especially when it is considered that the castings must have a very smooth surface. The operation of the sand-handling and distributing system is continuous during the working day, and all its units are coordinated so as to obtain maximum efficiency. The sand is reclaimed, screened, tempered, cooled, aerated, and delivered to hoppers directly over the molding machines.

Replacement sand, either in the form of reclaimed sand or natural sand, is fed to the mechanical systems through a gravity-discharge bucket elevator, delivering it from the foundry floor to the system sand storage located on the top floor of the building.

Sand from the shake-out is cleaned by passing over a reciprocating screen and magnetic separator, which removes all iron shot, sand pellets, and other foreign matter before it falls to the distributing belt. The backing sand is distributed uniformly on the mixing and tempering floor below by the aid of an automatically moving plow located over the distributing belt, and, after tempering, the sand is mixed and delivered to the backing-sand hoppers located directly over the molding machines.

Facing sand is made from mulled backing sand with the addition of a small amount of either reclaimed or natural sand. A battery of three mullers is used for this purpose, each equipped with suitable bucket loaders and discharging doors for quick action. The backing sand used for facing is delivered to a sand storage over the mullers by a cross-belt conveyor and bucket elevator from any one of the main distributing belts. After tempering and mulling, the sand passes through a centrifugal aerating machine to storage hoppers for delivery to the various facing-sand chutes.

Green core sand is mulled and delivered to the core machines in exactly the same manner as the facing sand.

Mold-Conveying System

It is important in a continuous system of this nature that the speeds of the various conveyors are properly synchronized. In the system described, the speed of the mold conveyor is the controlling factor, and is adjusted to suit the mold requirements by reducing or increasing it as the work varies.

The mold-conveying equipment consists of a series of trays suspended from an overhead conveying system. Four molding machines are located on each side of the mold conveyor, with a total of eight machines to each unit.

After pouring, the molds are conveyed to the shake-out, which is located on the third floor of the building. Here the castings are removed from the sand, and the empty flasks are returned to their respective trays. The sprues and gates are removed from the castings and delivered to industrial charging cars by a cross-belt conveying system; the sand falling through the shake-out grate bars is returned to the tempering floor as previously indicated. The average time cycle for a complete revolution of this unit is 20 min, with an elapsed time of 10 min from the pouring to the shake-out stations.

The jarring of the sprues and gates in falling to the conveyor loosens the sand on them, and this passes through a screen to the sprue-sand receiving storage for reclamation.

The operations of pouring, shaking out of the molds, removal of the castings, and the return of the empty flasks are accomplished while the mold-conveyor system is in motion, all operations being performed at a uniform rate so that no time is lost.

The fact that the various units of the system can be operated independently and that the speed of each unit can be controlled within reasonable limits adds the desirable amount of flexibility to the system.

The sand that accumulates in the sprue-sand storage is reclaimed by passing it over an electric vibrating screen. This separates the sand into two grades—that retained on the screen is discarded, while the other, which is the larger part, is collected and delivered to the system storage, and later bonded with finely pulverized clay.

Core Handling

The cores made in the foundry are of two kinds: green-sand cores and dry-sand cores.

Green-sand cores are used wherever possible because of the greater economy secured from the standpoint of labor and material costs. The core machines are located adjacent to the molding machines, and the sand is delivered to them directly from the floor above with a minimum amount of handling.

Miscellaneous and complex cores are baked. In order to minimize handling, the core ovens and benches are located only a short distance from the molding machines. The silica sand is delivered to the core room in skid boxes from an inside storage bin, and here it is mixed with the proper amount of core binder and delivered to the core makers. After baking, the cores are placed on portable racks and delivered to the molding machines on specially constructed hand trucks.

Cleaning Section

The design, size, and mass of castings used in the manufacture of sewing machines are readily adapted to tumbling, and for this purpose metallic shot and stars are used as abrasives for removing the molding sand in the cleaning operations.

The cleaning room is located in the west section of the building and on the fourth floor, which is on the same level as the third floor of the east section, and is adjacent to the shake-out stations of the mold-conveyor systems. Instead of carrying the castings to the tumbling barrels, which are of the friction-drive type, the tumbling barrels are brought to the shake-out stations, the shake-out operators merely hooking the hot castings from the shake-out gratings into the tumbling barrel. When the tumbling barrels are loaded and closed, overhead traveling cranes pick up the barrel and deposit it on the run.

This section has a total of 80 tumblers, which are divided into a series of eight individual lines of 10 each, and the construction is such that any tumbler may be run independently of all other tumblers.

When the cleaning operations have been completed, the crane delivers the barrels and castings through a hatchway to the finishing section located on the third and second floors.

The loose sand resulting from the tumbling is delivered by a belt conveyor to a refuse-storage bin and dust collector at one end of the building and later removed to open-top cars without further rehandling.

Finishing Section

In this department the tumbling barrels are unloaded and the castings delivered in skid boxes to the filers, grinders, and polishers, and after the work has been completed it is delivered to the first floor ready for shipment. Some castings are shipped to the machinery departments directly after cleaning; this depends on the use of the particular casting.

Electric Trucks

In handling materials an ideal condition is obtained only when the system is properly organized and the materials are moved as rapidly as they are ready for succeeding operations. For this purpose electric trucks are coordinated with the mechanical units for the routing of all materials.

Concrete and cast-iron floors throughout the foundry permit the extensive use of electric trucks and are an important factor in reducing the maintenance cost.

Electric trucks are used because of their flexibility, and cover a wide range of handling problems. Specially constructed electric trucks equipped with large built-up hopper bodies and bottom-discharge doors are used for delivering facing sand. Electric lift trucks are used extensively for delivering castings and in disposing of general refuse accumulations, and when not in use for routing work may be applied to other handling activities. Each truck is scheduled and the drivers know exactly what is expected of them.

FOUNDRY ORGANIZATION

In studying the management organization in a continuous foundry of this nature, it must be remembered that the foundry is but one of a number of departments in the plant and is governed by the general factory policies.

The foundry and pattern departments are closely associated with each other and are under the general supervision of an assistant factory superintendent, who acts in an executive capacity, directing the activities of both departments. Each department is under the direct supervision of a manager, but there must be close cooperation between the two in order to develop the greatest efficiency.

Other members of the organization include the general and maintenance foremen, bookkeeping and stock-section staff, and other sectional foremen in charge of productive labor, such as melting, molding, core making, cleaning, and finishing.

The foundry is operated as if it were an independent business. It is charged with factory overhead such as insurance, taxes, interest, rent, repairs, depreciation, and power; it is debited with all raw materials and receives credit for the finished castings from all receiving departments.

MANAGEMENT POLICIES

During the building and organization of the continuous foundry it became more and more apparent that certain fundamental policies must be laid down in order that a high quality of product be maintained, the efficiency of the machinery be kept at a maximum, and the costs of production at a minimum. Some of these policies that may be of general interest will be outlined.

Foundry Executives' Weekly Conference

A weekly meeting of the foundry executive organization, together with the members of the factory engineering staff directly interested in foundry work, is held for the purpose of discussing current foundry problems of quality, operation, and new development. The minutes of these meetings, a copy of which is sent to the works manager for his information, are filed as progress reports. This plan has proved very valuable in broadening the vision of the entire organization and in emphasizing the more important foundry problems. The organization is kept informed of all new developments in foundry practice outside of our organization by convention reports and technical papers which are discussed at these meetings.

Pattern-Equipment Conferences

The importance of properly designed and constructed patterns cannot be too strongly emphasized, and to insure this result, close cooperation between the foundry and pattern department is absolutely essential. Conferences between the managers of the two departments are held daily, and all matters of general policy are referred to the assistant factory superintendent.

The assistant factory superintendent is in constant touch with the factory production office to enable him to provide in advance for all new requirements.

Engineering Advice and Development

Engineering control and development is an important factor in the scientific development of the foundry, and while the latter has its own organization of trained men, it receives the benefits of engineering from the factory engineering departments and laboratories, consisting of mechanical, electrical, civil, chemical, and metallurgical departments.

The chemical and metallurgical departments are closely associated with the foundry, both in routine control and in development work. In these departments routine analyses of all coke, limestone, and pig iron are made, and the quality of the iron is further controlled by Brinell hardness tests and microscopic examinations. The detailed sand analysis is made in the chemical laboratory, but a sand-testing laboratory operates in the foundry to control the moisture, permeability, and strength of the sand in daily use. By instituting a control of this nature the quality of the sand can be corrected before it is used, and excessive foundry losses can easily be prevented.

Development work is continuously in progress in the metallurgical department and is converted into practical results by cooperation with the foundry organization.

Production Control

Production control in a continuous foundry resolves itself mainly into a properly planned schedule and routing system, shipping-section cost system, purchasing division, and stock room. Records and statistics are essential in operating a continuous foundry of this character and are of much more importance than in the ordinary foundry.

Scheduling and Routing. The proper routing of parts through any department is obtained only after a careful analysis of the requirements and by having them travel in a straight line to the shipping points or stock room accompanied by some form of identification.

The factory production department regulates the flow of work from the foundry by means of an order system, and governs these orders according to the demand of the product, from figures obtained through the factory management. In routing the castings through the various departments they are assigned part numbers in order to facilitate clerical labor.

The foundry orders controller is responsible for production, and it is his duty to acquaint himself with stock records and weekly and bulk orders, so that he is in a position to have parts made either for production or for stock requirements.

Orders entering the department are generally issued on two forms: a weekly order, which is a standing order for a definite number of castings to be delivered each week, and bulk or quantity orders. Bulk orders are given a due date, and the work is arranged in strict accordance with the schedule.

In starting the work through the department the orders controller issues a production order in triplicate: one to the foreman that has charge of manufacturing the castings, one to the pattern storage, thereby applying for the pattern, and one to the shipping clerk. After receiving the pattern the foreman produces the castings, which automatically pass through the successive operations until they reach the shipping station. The shipping clerk, having received notice of the castings, is responsible for their

proper destination. After the pattern has been returned to storage and the parts have been shipped, these three production orders are returned to the orders controller, who destroys the duplicates, but retains the original for reference.

As most of the operations in the continuous foundry are paid for on a piecework basis, it became necessary to devise some method for crediting the molders and other piecework operators with the actual work they had performed. The molding machine and shake-out operators receive credit for their work through a system of checks which are numbered corresponding to the molding machines, the operators placing one check on each mold made. After the unit has moved to a different section of the foundry, the checks are removed, sorted, and later delivered to the office for counting and recording. These results are entered daily by the foreman on the payroll work sheets indicating the part numbers, operations, quantity of castings, and piecework rate of the work performed by each operator. At the end of each week a summary is made deducting the total defective castings from the total number of castings produced. The payroll is determined from these work sheets, which are delivered to the factory payroll department, where the extensions are entered on the factory payroll sheets, and later returned to the foundry office for their permanent record.

All operators receive their pay checks weekly, from the factory payroll department through an identification ticket issued by each foreman under whose direction the work was performed.

A ticket system is used in the cleaning department for checking the tumbling operations. Tickets are placed on each tumbling barrel indicating the part number, tumbling time, and also the packer's number. Aside from indicating the tumbling time, it shows the operator who is responsible for the packing operation. After the castings have been delivered to the operators in the finishing department, they are counted, and a duplicate foundry inspection ticket is placed with each lot of completed castings, one acting as a follow ticket, which remains with the castings throughout the successive operations until they are ready for shipment, while the other acts as a stock office ticket, which is retained by the foreman and is checked against the record of the daily work slips of each operator. After the foreman has checked both the stock and work tickets, they are entered on his payroll work sheet after the piecework rates are checked in the foundry office. These work sheets are then routed in the same manner as the work sheets for molding operations.

Shipment of Castings. The foundry is connected with all receiving departments, factory production, factory cost, and factory bookkeeping departments through the large amount of detail work necessary in the shipping and receiving of castings. An example of this work is as follows:

After the castings reach the shipping department, the clerk removes the follow ticket for his record and substitutes two shipping tickets, which are delivered to the receiving department with the castings; one duplicate, however, is retained by the clerk. The receiving department, after checking the quantities and part numbers on the tickets, signs the original and returns it to the foundry office. At the end of each week all tickets are summarized and delivered to the receiving department for their signature. This summary is made in triplicate: the original is delivered to the receiving department, one copy goes to the factory production department, and one copy is retained in the foundry shipping department. The receiving department, after signing the original, delivers it to the production department, and the latter sends its copy to the receiving department. In this way errors due to the quantity of the castings delivered are less likely to occur. Entries are made of shipments by each of the departments concerned; the receiving department does this to show the number of castings received, the production department to show the movement of stock, and the foundry department to eventually receive credit for the castings delivered. Bills containing the part numbers and quantities of the castings delivered are sent to the production department periodically for checking, and later, after pricing and extending, are delivered to the cost and bookkeeping departments for credit. In this way a careful check is maintained on the production, movement, and cost of all castings.

Stock Room. It is obvious that with a variety of 1500 to 2000 different castings made in this continuous foundry—some of which are required in large quantities weekly, while others are in smaller demand, and particularly as some of the castings are small, perhaps as many as 30 or 40 castings being produced per minute while the demand calls for perhaps only 10,000 per week—some latitude of actual production must be allowed. To allow for this intermittent demand for certain individual castings and for the overmolding capacity of others, a foundry stock room was inaugurated for the storage of surplus castings. As a general policy we have established maximum and minimum quantities of the various castings that may be carried. It is our aim to keep close to the minimum quantity set in order to have as little rehandling as possible, and also to keep the carrying charges as low as possible.

It is true that greater efficiency can very often be obtained if the castings are shipped to the various receiving departments directly after manufacturing, and it is our intention to do this whenever possible, placing only the surplus in stock.

The stock room is located adjacent to the foundry and with sufficient aisle space for receiving and delivering castings. The large-size castings are placed in storage bins, while the smaller castings require a properly labeled rack and shelf layout. Each casting has a certain rate of demand, and the most active classes of work are given the most desirable and advantageous positions.

A complete list of the quantity of each item is kept at both the stock room and the foundry office. In this way it is possible to keep an accurate record and perpetual inventory of all stock and also to reduce errors due to mixed stock, mislaid stock, and the receiving of incorrect stock. The office receives notification of all stock movements through department shipping tickets.

Corrosion prevention is a most important item when stock has accumulated, and we aim to keep the temperature of the room at 70 F in order to minimize rusting of the parts.

Inspection of Castings

The quality of the casting produced is considered paramount, and for this quality demanded the unit foreman is held responsible. He is provided with an assistant whose duty it is to constantly inspect castings for defects, and by reporting to his superior, cause the remedy to be applied. This assistant foreman from time to time takes molds from each molding press immediately after pouring, not waiting for them to take the usual time and course through the shake-out, has them immediately sand-blasted, and performs a rigid inspection.

The operators at the shake-out also give the castings as close an inspection as possible, reporting immediately to the unit foreman such defects as they find, but naturally the main inspection comes after the castings are tumbled, as defects are then more easily discerned. We have found that the cheapest and most effective method of inspection is to pay for all operations on castings subsequent to the tumbling operation, on a basis of good castings produced. Thus the grinder removing fins and gates does not get paid for grinding defective castings, nor the polisher for polishing defective filed castings. While this policy may have the effect of making the operators overcautious and causing them to set aside work that later may be saved, nevertheless we find it better to err on the side of caution than to allow castings to pass

to subsequent costly machining operations and later to be discarded.

In addition to the foregoing inspections, a constant check on inspection is being made by the foreman of the cleaning and finishing departments. A final inspection by the foundry shipping department is made before the castings leave the foundry.

The foreman and operators are constantly informed of defective work. Foundry discount sheets, which constitute a combined record of the inspections, are distributed to the molding foreman each day, with a record of the part numbers, amounts, and defects, classified in detail. The relation between the percentage of defects and the moisture, permeability, and strength is charted on a bulletin board, for the benefit of both the foreman and the management. In order to acquaint the operator with his particular defects, a discount record is kept on the blackboard of each molding machine.

We believe that this type of inspection is necessary in mass production, particularly, for the type of labor employed in the foundry.

Maintenance

In order to obtain long life and uninterrupted service in operating foundry mechanical units and in the mechanical transportation of materials, the maintenance of the machinery is of supreme importance. In the foundry described, approximately 5 per cent of the organization is employed in this activity, and the main function of the maintenance section is to inspect and repair all mechanical and electrical equipment.

The complete foundry molding system, as previously described, is divided into five independent units, the maintenance of each unit being in charge of its foreman. In addition to the foreman there is a unit operator, whose duty is to watch the mechanical-conveying and sand-handling system of his unit, to see that all moving parts are constantly lubricated, and to report promptly to the foreman any sign of weakness or excessive wear that has developed.

In addition to the servicing of the system units during the operating hours of the day, a careful weekly inspection is maintained on all mechanical and most of the electrical equipment.

The foundry is equipped with a machine shop for the maintenance and immediate repair of all minor equipment. This is essential because the shutting down of important handling units for any length of time means a loss in both production and in time-work productive labor. All minor electrical and mechanical repairs are made in this section, while other repairs that are too large to be handled here are made by the factory electrical department and tool room.

Aside from the unit operator the foundry maintenance section employs a pipe fitter, an electrician, and a number of general repair men. The general repair men repair or replace all worn and broken machinery and make all other minor miscellaneous repairs, such as resurfacing flasks and repairing tumbling barrels. All air and hydraulic lines are serviced by the pipe fitter, while the electrician makes all minor electrical repairs, inspecting and lubricating all electrical equipment such as motors, electric trucks, and safety switches.

The cranes and elevators are under the direct supervision of the factory electrical department. The equipment receives a continuous inspection by the operators, as well as receiving a careful weekly inspection and servicing, and a weekly report is made on the condition of all such equipment.

The machine operators in the molding and finishing departments are to a large extent responsible for the condition of their machines, but in case of failure the foundry maintenance section is notified immediately.

The number of spare parts necessary for the maintenance of the mechanical units and other handling machinery has been reduced to a minimum, by producing standard interchangeable parts.

Suitable exhaust equipment is an important feature in reducing the dust present in all foundries. A cyclone dust-collecting system confines the dust from the cleaning and finishing sections for easy disposal and materially reduces the maintenance cost of the machinery and at the same time reduces the hazard to health.

Standardization

In mass production, standardization is important, because it eliminates waste and results in economies through a better and more uniform product at a lower cost. For this reason it is the general policy to standardize parts as far as possible.

Castings, equipment, and raw materials have been standardized. The most essential feature in the standardization of the product is accuracy and interchangeability in order that the parts shall fit properly, but the limits of any part will vary according to the requirements. In this respect, the shrinkage of the metal must be considered and the pattern increased in size accordingly, if the castings are to be produced within proper limits.

Flasks, pattern plates, and a large number of parts required for the various units of the continuous system are interchangeable. All raw materials such as coke, limestone, pig iron, and scrap are purchased according to standard specifications.

Cost-Accounting System

A cost-accounting system is of vital importance as a means of visualizing conditions and can be secured only by records from a comparison of standard and actual costs. Due to the enormous quantities of materials consumed in large foundries, items that ordinarily might be considered insignificant assume importance in the final analysis of costs. Therefore a system that keeps accurate records is an absolute necessity in producing efficient management.

The cost system instituted in this foundry shows, essentially, the cost of the castings and the consumption of materials, and it measures the efficiency of labor by comparison and acts as a guide for correcting faulty methods of manufacture. The accounting method is separated into three main divisions, as follows:

1 The foundry operations are classified into sections depending upon the type of work done
2 Each section is subdivided into separate accounts
3 A method is used for applying indirect and overhead expenses directly to the section involved.

In order to differentiate between the types of work, the production costs are classified as follows:

1 Melting section
2 Molding section
3 Coremaking section
4 Cleaning section
5 Filing, grinding, and polishing section
6 General expense
7 Special charges.

A summary of the cost of production is prepared periodically for comparison and the accounts are condensed, supplementing the summary with additional records that give costs in greater detail. If there is an abnormal fluctuation, the cause for this is determined and in many cases corrected.

A yearly report on the cost of production is also made for the benefit of the factory management in order to determine the efficiency of operation and also to determine the advisability of making fundamental adjustments and improvements.

Cost of Individual Castings. The average cost of manufacturing castings is insufficient, and it is essential that a further analysis

be made by studying the cost of producing castings from specific patterns. By the aid of job costs the management has a guide to aid in producing castings at a minimum. A record sheet is kept of the cost of each different part, giving detailed information of operations, prices, and cost per 100 lb.

Labor is important, because it is one of the most variable factors in contributing toward success or failure. Since the costs of individual castings are largely dependent on labor costs, incorrect results may lead to disastrous cost finding. Rate setting for molding and core-molding operations acts as a means for controlling direct labor costs. The molding labor and molding piecework rates are established by the department head after conferring with the foreman, and these are based on experience with similar work, the volume of sand, size of the flask, number and size of the cores, core-setting time, type of patterns, and the number of castings that can be produced per day.

In a continuous system it ordinarily is difficult to obtain accurate results on time-work productive labor and to connect this directly to the individual castings, due to the fact that one operator distributes his time over a variety of patterns. We have found that a convenient and accurate cost can be established for this type of labor from the production of both the individual and total number of machines operating on each unit. This is called the molding-press day and is defined as the number of molds produced each day on one molding machine. This is the basis of all time-work productive-labor costs from molding to shake-out. In this way an accurate cost and cost comparison can be established for any particular casting; also there is less clerical effort necessary in order to obtain accurate results.

The rates in the filing, grinding, and polishing section are determined by a combination of rate setting and the results of previous records.

The volume of detail necessary for an accurate determination of costs is also valuable for statistical purposes, especially for comparison between the different factories operated by the company.

Purchasing. All materials are purchased through a central purchasing department, which keeps in close contact with the organization. Technical specifications have probably been the most notable advancement in the purchasing of equipment and supplies and are used wherever possible.

It is the intention of this department to purchase products in the most suitable quantities and in the most economical amounts.

Records

In large organizations records are of major importance in presenting the facts. A detailed cupola report is made daily for the benefit of the management, and it is also used as an office record for compiling the detailed weekly summary reports. The daily cupola report shows the iron mixtures, analyses, physical tests, and the melting ratio, while the weekly summary reports show the consumption of all raw materials, raw material stock on hand, and cupola data, as well as a detailed tabulation of all defective castings throughout the factory.

Safety Methods

The nature of foundry work in general, and particularly where machinery is employed, requires that a large amount of attention be given to safety methods in order to minimize accidents and personal injury.

Throughout the system safety has been carried out in detail by the application of mechanical safety devices consisting of safety control switches, automatic stop switches, safety clutches, and safety appliances. Each unit can be stopped immediately by manually operated safety-switch controls located at four different sections equidistant from each other and at points where workmen are stationed. Automatic safety stop switches have been installed to prevent possible accidents from falling flasks on that section of the system where the mold-conveying unit returns to the first floor. The stop switches are placed at definite points so that flasks that project from any of the trays on the conveyor unit, constituting a hazard, will contact with the switches, automatically breaking the circuit and stopping the system. Each sand-distributing unit is provided with a safety clutch in order to disconnect it from the sand-conveying belt whenever necessary. Metal protecting guards are used extensively for protection against moving machinery such as gears and grinding wheels. Operators in all sections of the foundry are provided with other safety appliances such as leggings, goggles, and respirators.

Because the iron is poured at definite stations and the molds are conducted away as quickly as possible, the smoke and gas are removed before they can have any effect on the men. In addition, the operators at the shake-out have been further protected by the installation of fan equipment in order to afford more ventilation, particularly in the summer.

Education in safety is important, and we believe that bulletin boards, properly located, carrying photographs with legends of what may occur, have a psychological effect on the men, tending to make them more cautious in their work.

A branch of the factory hospital is located in the foundry, for the immediate treatment of the more common accidents. A nurse is in charge, but is under the supervision of the factory physician. The factory management is kept informed of this work through records and reports of the injuries sustained by the workers.

ESSENTIALS FOR EFFICIENT MANAGEMENT

Maximum efficiency from a continuous-production foundry can be obtained only by a careful consideration of certain essential facts, such as these:

1. The work must flow in straight lines to the shipping points
2. Responsibility must be fixed, particularly with reference to subordinates
3. Engineering research and development are necessary for improving the quality and reducing the cost of the product
4. The grade of work produced must be considered paramount
5. A well-designed production-control and cost system is fundamental; it should show by records the location and the quantity of work in the department as well as accurate detailed cost data
6. Proper maintenance and safety devices are essential.

CONCLUSION

Maximum efficiency from a continuous system, as measured by the cost of production, can be obtained only through scientific management.

MAN-55-6

Fundamentals of Training

By G. GUY VIA,[1] NEWPORT NEWS, VA.

Fundamental principles involved in a modern training program are outlined. Beginning with an accepted definition of training, certain postulates are set up: (1) The careful selection of the learner. (2) The careful selection of the instructor. (3) The development of a suitable system of grading. (4) The analysis of the business for its training content. (5) The objectives of the training program. In selecting the candidate for training, attention must be focused on (*a*) physical, (*b*) manual, (*c*) mental, and (*d*) moral qualifications. A certain minimum of each capacity should be evident. The instructor must be a craftsman, a teacher, a psychologist. He must be a leader, an adviser, and a friend. A method of grading somewhat out of the ordinary is developed from Richard's formula for effective training. This system uses the performance of the average worker as a standard, rather than that of an imaginary ideal worker who has never existed. The instructor should analyze the business thoroughly for its instructional content, regrouping the units according to the learning difficulty from simple to complex. This analysis may often be turned to useful account by the thoughtful executive in comparing the worth of various employees, reviewing the processes of the business, etc. The paper is concluded with the reminder that the perpetuation of a business depends upon the continual absorption of new blood, which gives to the study of training an unusual significance.

TRAINING has been defined as the process of developing through a series of progressive experiences an ability on the part of a learner to do something that he could not do before. This definition embraces every field of human endeavor, each with its manifold activities, and offers a secure footing on which to erect a most satisfactory training program, whether simple or elaborate. The newly employed cook in the kitchen must receive training in the dietary habits and peculiarities of her employer's household; the new bookkeeper must needs be trained in the routine of the debits and credits of the business; the new machinist must become familiar with the methods, tolerances, etc. of the shop; even the newly appointed manager must himself learn to render wise decisions in the complex situations that are continually arising in the discharge of his duties. This business, then, of "developing ability through a series of progressive experiences" would seem to have a wide application, and an understanding of the fundamental principles involved should go far toward the elimination of wasted time, effort, and material in this increasingly important field of engineering activity—training.

Two phrases in the definition cited are worthy of consideration: the first, "developing an ability," and the other, "through a series of progressive experiences." The development of ability implies, first of all, careful selection of the novitiates to weed out those who by reason of mental or physical imperfections may be unable to profit fully from the training offered. Better yet, if choice can be limited to those who are equipped to profit most from the opportunity offered, greatest efficiency is secured from both a training and a performance standpoint. Waste of time and effort may be averted here. It implies as well the careful selection of those who are to be assigned to the duty of instruction. Poor instruction is profitless instruction, to both beginner and employer, and teachers of talent and ability are not common in the world of business and industry. It implies also a carefully determined method of grading, fair to both employer and employee, in order that each may know whether actual and satisfactory results are being secured.

The phrase "through a series of progressive experiences" sounds innocent enough when spoken and looks equally simple in print, but what a useful and complex range it unfolds to the patient investigator as he undertakes to apply it to the practical phases of business or industry! "Series"—one after another, covering the entire field of the business or industry; "progressive"—graded in difficulty from simplest to most complex; "experiences"—the multitudinous tasks, jobs, or operations that form the warp and woof of the business fabric. Here, then, is involved the complete analysis of the industry, its processes, the danger hazards, the trade terms used, the mathematical computations, the applications of the principles of science, perhaps an understanding of human behavior. These and many other fields of knowledge must be explored, charted, and rearranged before the text book which constitutes the "series of progressive experiences" can be put into the hands of the learner. The task is stupendous, but both the direct and collateral benefits of determining first the differentials of the industrial equation and the subsequent reintegration of those refined differentials will be instantly apparent to the engineering or managerial mind.

Unfortunately, this definition of training is not complete. The beginner's mind may be well stocked with carefully presented and well-digested knowledge; his hand may possess the last refinement in skill and cunning; but unless there is created in him an ever-present urge to perform gladly, willingly, and pridefully at his daily task, a most important training fundamental has been neglected. The development of morale must have prominence in any training program, real morale as distinguished from misdirected and frequently overdone paternalism. The machine may emancipate the mind and the hand of the worker, but nothing can substitute for his heart. With this thought in mind, the definition might be revised to read: "Training is the process of developing through a series of progressive experiences an ability on the part of a learner to do willingly and pridefully something that he could not do before."

---

[1] Supervisor of Training for the Newport News Shipbuilding and Dry Dock Company. Mr. Via was graduated from the Virginia Polytechnic Institute in 1910 with the degree of B.S. in Electrical Engineering, entering the employ of the Westinghouse Electric and Manufacturing Company at East Pittsburgh, Pa. In 1911 he joined the faculty of the Newport News High School, taking charge of the department of mathematics, and being appointed assistant principal in 1912. In 1913 he entered the employ of the N. N. S. & D. D. Co., being assigned to special research in the purchase, storage, and distribution of materials. He was appointed supervisor of apprentices in 1919, and has since been engaged in the work of training employees.

Contributed by the Committee on Education and Training for the Industries and presented at the session of the Management Division at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Objectives of Training

From these introductory remarks on the definition of training, there may be taken the following interesting phases for more detailed study:

1 The careful selection of the learner
2 The careful selection of the instructor
3 The development of a system of grading which is founded in fact and not on guesswork
4 The analysis of the business to determine what shall be incorporated in the program of training
5 The process of developing: (a) the hand, (b) the head, (c) the heart.

These last three items—the hand, the head, and the heart—may be considered the three objectives of the training program, for every activity associated with training will be consciously directed at the development of one or another of this important trio. Does this or that project further the development of the hand, the head, or the heart of the learner? There is here a convenient yardstick by which one may measure the worth of any training proposal. Can this or that instructor reach effectively the hand, the head, and the heart of the learner? The length of shadow which the instructor casts on this objective screen determines his fitness for the assignment. Does this or that applicant possess the necessary requisites of hand, head, and heart to profit most from such a program? What an effective mesh to separate desirable wheat from the human chaff pile! From every angle the excellence of the program may be measured by the degree to which it approaches the utmost fulfilment of these three desired objectives.

Selecting the Learner

a Physical. Every human being represents the integration of an infinite variety of tendencies and capabilities, good, bad, and indifferent. Clamoring at the gates of business and industry are dull individuals and intelligent, educated and ignorant, fat and lean, short and tall, handsome and ugly, with every possible variation in between. Judicious choice is indicated at every turn. Every task demands certain physical and mental qualifications of the operator which cannot be ignored except with unsatisfactory or even disastrous results. Why waste time training a crosseyed girl to sell millinery? On the other hand, the same girl might become an expert designer in the back room and be most happy at her vocation. The sight of a 200-lb electrician clinging to the top of a tall, slender ladder will cause even the most perfunctory safety engineer to look the other way, while the same man snaking a heavy cable through a conduit makes a pleasing industrial picture. To be sure, physical limitations are in evidence on every hand and must assuredly be given consideration in selecting the learner.

b Manual. Manual dexterity cannot always be acquired. Harry B. comes from a long line of forebears who were mechanics and has every appearance of becoming a satisfactory craft apprentice, but he is not. Somewhere between Harry's mind and his finger tips there is faulty synapsis, and Harry's fingers will not obey Harry's brain. The results are deplorable, both to Harry and to his employer. Arthur N.'s father is a nationally known expert in machinery operation, as were his other ancestors. Arthur also has brothers who are gifted artizans, but he will never acquire craft skill. Arthur's fingers obey his will, but reluctantly! Arthur's motor-mental hook-up is awry.

These defections may often be brought to light by a study of the applicant's previous school record considered in connection with certain simple manual tests for determining digito-muscular control. Such an applicant's medical history will sometimes show epilepsy, fainting spells, etc. all of which information is concealed by the applicant himself and is discovered only after painstaking investigation.

c Mental. Does the task require the frequent exercise of judgment and intelligence? The mental capacity of the applicant then assumes prime importance, and a careful investigation of this faculty is indicated. If available, the applicant's previous school record, obtainable from the school principal, is illuminating. It may sometimes be advisable for the prospect to be given an intelligence test on the spot to measure this important factor in his qualifications, and while the results are not always infallible, they may at least be relied upon to eliminate from consideration those who are hopelessly inferior mentally.

Some years ago a certain large industry made a study of the correlation between the intelligence of its apprentices and their training progress. Groups of 40 boys, each in two widely different crafts, were chosen for study. Each apprentice was given an intelligence test and classified in one or the other of four divisions, according to the results obtained.

The ten highest scores were segregated in group I, the ten next highest in group II, and so on. The training averages of these same boys over a period of several months were treated in the same manner, the ten best apprentices being segregated in group A, the ten next best in group B, etc. It was expected if correlation existed that the majority of the brightest boys would be found among the leaders in the shop, while the dullest boys would evidence retarded progress in craft training. How well these expectations were borne out may be seen from a study of the distribution chart, Table 1.

TABLE 1 SKILL-INTELLIGENCE CORRELATION

Shop group	Intelligence group I	II	III	IV
M— Trade				
A	5	1	3	1
B	3	4	1	2
C	3	3	0	4
D	1	1	4	4
F— Trade				
A	6	3	1	0
B	1	4	4	1
C	2	2	2	4
D	1	1	3	5

This industry has since methodically eliminated from consideration those applicants for apprenticeship who are unable to pass a satisfactory intelligence test, and has chosen only those whose scores were average or better.

d Moral. No longer can business or industry afford to ignore the habits of its employees, both during and after work hours. Conduct is a sure index to character, and human behavior mirrors the inner man. Industry is interested in character quality, if for no other reason than the maintenance of morale. A better reason is that men of character build products of character. A closer scrutiny of the habits and morals of the applicant is indicated. There is here an apt application of the old adage concerning the bent twig and the matured tree. Due consideration for the third objective, heart, will necessitate the elimination of the "rotten apple in the barrel," for those qualities of loyalty, punctuality, regularity, and service which industry demands today are not consistent with weak moral fiber. The risks involved in the employment of individuals of faulty character far outweigh their probable ultimate usefulness.

Selecting the Instructor

For years it has been the custom of industry to delegate the duties of training to aging employees who were giving ground in the production battle, the first step toward their eventual retirement; and while these men have done the best they could with a task which is now recognized to have been far beyond their capacities in most instances, industry today demands far superior

results from the training dollar. In the first place, manners and customs vary widely from generation to generation, especially the manners and customs of youth, and an understanding of the impulses and reactions of youth from whose ranks will be drafted the greatest amount of raw material for training is imperative. It is most unlikely that the veteran about to be retired has maintained a sufficiently close contact with young people to appreciate the psychology of modern youth. Even though a parent, he has probably long since thrown up his hands in despair over this same problem in his own home; and yet youth today is on the whole as clean and wholesome as ever. They have simply discarded the art of dissembling, which was so prevalent in days gone by, and yield little to the cloak of modesty. To this extent the problem of the psychologist in training is simplified, and the successful instructor must of necessity comprehend at least the fundamentals of this science. Teaching is both a science and an art, and the veteran undertakes a new field of endeavor too late. Years of conscientious effort and study are necessary if one is to become even a passably proficient instructor, and the science of pedagogics is not to be mastered overnight.

It is axiomatic in training that skill cannot be transferred; it must be acquired. Hence the years spent by the veteran in acquiring adeptness will be of no avail unless combined with the other qualifications for successful instructional ability, a rare natural combination. It would seem unfair then to delegate such a responsibility to elderly employees, though it must be borne in mind that exceptions, and ofttimes notable exceptions, do occur. As a rule, however, the young and ambitious craftsman willing to begin the study of psychology, pedagogics, and such necessary kindred subjects offers the greater probability of success in this work. He or she is not so far removed from youth itself as to have lost contact. An intensive course in teacher training (in which either the State or Federal Board for Vocational Education is willing to participate) will provide the necessary fundamental experience for the new instructor, and results thereafter will depend on his inherent skill, his patience, his diligence, and his intelligence.

A final word about the instructor: It should be borne in mind that he must not only be able to tell about his craft in striking manner, but many times daily he will find it necessary to demonstrate his ability as a craftsman. To do this he must himself be a skilled artizan and a master of his vocation. Another would be hopelessly lost the first day. His influence over the learner will be far-reaching. Is the proposed instructor the kind of person to influence youth? Is his head right? His hand? His heart?

System of Grading

The measurement of human effort presents a problem which is most baffling to solution. No two people ever see a definite occurrence alike, as millions of jurors in the courts can testify. Since daily work performance is merely a long series of definite occurrences, it is most improbable that there shall ever be found two people whose opinions of a beginner's progress will coincide. And yet, in all fairness the learner is entitled to know that his effort is not being spent in vain, and management should always be relieved of incapacity promptly. The rate at which training is proceeding is then of importance.

Training Curve

The study of thousands of performance records of learners shows a remarkable approximation of similarity; in fact, a fairly definite training curve. Beginning at or about zero, the curve mounts fairly rapidly at first, gradually flattening out in the midsection, and finally resuming its upward trend at an accelerated pace to completion. (See Fig. 1.) The reason for the plateau between the two slopes still remains a matter of conjecture, although some ingenious solutions have been suggested. Nevertheless, during the training period of every worker there comes a time when progress seems to cease regardless of effort and when despair possesses the learner. Time, patience, and encouragement in this crisis bring renewed hope to the discouraged worker, and eventually satisfactory progress is resumed. Whatever system of grading is chosen should be sufficiently accurate to reflect the true condition of affairs for the guidance of the instructor. As the usual 0–100 per cent method is seldom more than guesswork, the following method is offered as an improvement.

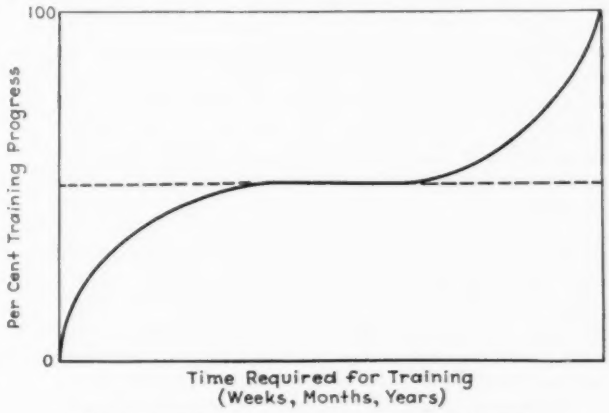

Fig. 1 Theoretical Training-Progress Curve

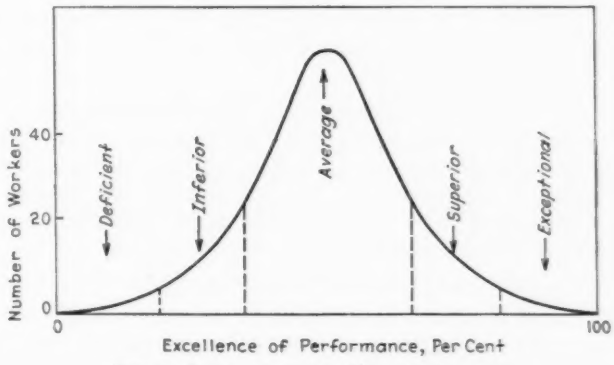

Fig. 2 Distribution of Worker Ability

Distribution of Ability

The backbone of any industrial organization is the average worker. Two-thirds of those who present themselves at the pay window will come within this classification. Half of the remaining third is made up of a few workers who are superior to him in general, and fewer still exceptional men who seem gifted with talent for continuously excellent performance. The workers in these three classifications constitute industry's money-makers.

Moving downward on the scale from the average worker, the remaining sixth may be classified under two headings of inferior and deficient. The inferior worker lacks something, job knowledge, manipulative skill, application, which renders his service somewhat less satisfactory, while the deficient employee lacks these or other qualifications in sufficient measure to make his retention on the pay roll questionable. Their effort is far less profitable. This distribution of abilities may be represented as in Fig. 2, and are classified as (1) exceptional, (2) superior, (3) average, (4) inferior, and (5) deficient. This table, then, provides a convenient yardstick by which one may scale the productive effort of the worker, and the adjectives chosen to describe

his several qualifications should be selected and arranged with these differences in mind.

Make-up of the Worker

A certain worker is spoken of as being a "good mechanic." Another is a "poor mechanic." Just what is meant by this distinction? Obviously both descriptions are generalizations, and each needs further analysis to determine what the qualifications are which cause one to consider the first worker "good" and the other "poor." Every human being represents the integration of a multitude of traits and characteristics—some prominent, others negligible; some inherited, others acquired. If one could accurately single out and evaluate each characteristic in an individual, he would acquire a true picture of that person. Of course this is impossible. At best one can only choose certain outstanding traits of aptitude and attitude which are desired in the worker and estimate the extent to which these traits predominate in a given individual. For instance, by observation it is known whether a man is lazy, slow, moderate, fast, or diligent, thus gaging his muscular effort. The results of his labor will evidence crude, mediocre, satisfactory, skilled, or expert workmanship—an index to his psycho-motor coordination. Is he enthusiastic, earnest, sincere, indifferent, or antagonistic toward the company's aims and policies? His conduct will reveal even the innermost impulses of his heart to the trained observer.

It only remains then to select certain indexes reflecting those traits which every worker is expected to possess in greater or less degree, and then to measure the amounts of these indexes which the individual in question actually has in his make-up. A fairly accurate picture will result.

Choosing and Evaluating Characteristics

In singling out these indexes, no better starting point can be found than that provided by Richard's formula, which states that effective training is the result of properly combining M, manipulative skill; T, technical knowledge; I, auxiliary information; J, trade judgment; and Mo, craft morale.

$$E = M + T + I + J + Mo$$

These five elements are evidently not all equal in weight, and these may be evaluated as one sees fit. For discussion, however, let it be assumed that a total number of 10 indexes is wanted ($E = 10$). The following is suggested as a fairly satisfactory distribution of weights:

M	4
T	1
I	2
J	1
Mo	2
Total (E)	10

Then select four indexes which reflect the worker's M, or manipulative skill. Five possible choices are given, although many others may be included:

Workmanship: "Quality of work produced"
Dexterity: "Readiness and skill in using hands"
Speed: "Time interval consumed in completing task"
Craftsmanship: "Reputation for trade ability"
Accuracy: "Ability to work within limiting measurements."

Technical knowledge, T, is the knowledge which the worker needs to perform satisfactorily the immediate task in hand. The carpenter cannot cut the joist unless he can read his rule. Reading his rule, then, is necessary to the immediate task, and this knowledge would be classified as T. The machinist must read a micrometer to work in thousandths. A knowledge of decimals, then, would be classified as technical knowledge for a machinist. "Confidence" certainly reflects the possession of this information and may be used as an index. If dimensional errors are made because of lack of this information, then "accuracy" may be listed here as well as under M, with the distinction that accuracy in M reflects muscular control and the errors would be small, whereas an inaccuracy in T would probably be an error of real proportions and would arise from ignorance. Other indexes will suggest themselves.

I, or auxiliary information, is that broad field of knowledge which provides a general background for craft accomplishment. Pure science, mathematics, economics, and sociology all contribute to a proper concept of industrial duties and obligations and provide a reservoir of information from which the worker draws from time to time in the performance of his duties. For employed intelligence, three indexes are suggested:

Comprehension: "Manner of grasping mentally"
Curiosity: "Anxiety for knowledge"
Memory: "Faculty for retention of knowledge."

Trade judgment, J, is ingenuity at task performance accumulated through the experience and observation of years. Some workers seem particularly gifted in this direction; others not at all. Two indexes are given for consideration:

Resourcefulness: "Capacity for finding or adopting means"
Originality: "Capacity for original conception."

Craft morale, Mo, is the ambition to excel. Beginning with the individual, it can be expanded to include group, shop, and company. It is reflected in both word and deed. Five indexes are noted:

Reaction: "Response to stimulus"
Attitude: "Indication of opinion"
Expressiveness: "Evidence of opinion"
Interest: "Attention with a sense of concern"
Initiative: "Ability for original conception and independent action."

Building Up the Report

The suggestions that have been offered are neither complete nor perfect. They are intended to point out a method by which certain characteristics in individuals may be chosen according to a definite plan and ratings made on these characteristics which will fairly represent the worker's worth. Selecting the proper number of indexes under each element of Richard's formula, a report might be built up as follows:

M (4 indexes)	1	Workmanship
	2	Dexterity
	3	Speed
	4	Accuracy
T (1 index)	1	Confidence
I (2 indexes)	1	Curiosity
	2	Memory
J (1 index)	1	Resourcefulness
Mo (2 indexes)	1	Interest
	2	Initiative

To complete the report, it is only necessary to select five adjectives to apply under each of the ten indexes, each group of five adjectives having a descriptive range from deficient to exceptional and weighted accordingly. To illustrate:

Index	Range	Weight
Workmanship	Expert	5
	Skilled	4
	Satisfactory	3
	Mediocre	2
	Crude	1

The completed report might then appear as shown in Fig. 3.

Comparing the Workers

It is to be noted that the middle adjectives, satisfactory and handy, are fairly descriptive of the workmanship and dexterity of the average worker, and would apply to approximately two-thirds of all employees. There are also two higher and two lower classifications in every instance.

In actual use the adjective is selected which best seems to describe each of the ten characteristics present in the individual, and the assigned weights are added to give a total sum. This sum in turn could be multiplied by the constant (2), to translate the score to a basis of 100 if desired.

A further refinement is recommended. If the average score for a group of workers be ascertained, and this average be divided

NAME.....

TRADE ABILITY (Aptitude)	CRAFT MORALE (Attitude)
WORKMANSHIP (M)	CURIOSITY (I)
Expert	Eager
Skilled	Inquiring
Satisfactory	Average
Mediocre	Passive
Crude	Indifferent
DEXTERITY (M)	MEMORY (I)
Adept	Exceptional
Clever	Retentive
Handy	Average
Clumsy	Fair
Bungling	Defective
SPEED (M)	RESOURCEFULNESS (J)
Swift	Ingenious
Fast	Clever
Standard	Reliable
Moderate	Ineffective
Slow	Helpless
ACCURACY (M)	INTEREST (Mo)
Exact	Intense
Accurate	High
Adequate	Normal
Faulty	Moderate
Inadequate	Low
CONFIDENCE (T)	INITIATIVE (Mo)
Inspiring	Diligent
Positive	Industrious
Certain	Willing
Uncertain	Listless
Lacking	Indolent

CHECK YOUR CANDID OPINION UNDER EACH HEADING

Fig. 3 Form Used for Reporting Learner Progress

into each individual score, a percentage will result reflecting the percentage of superiority or inferiority, according to the deviation from 100. Suppose the average score for a group of workers after multiplying by the constant 2 is 63.2. John Doe's score is 68; Richard Roe's score is 52.

$$68 \div 63.2 = 107.59, \text{ John Doe's percentage}$$
$$52 \div 63.2 = 82.27, \text{ Richard Roe's percentage}$$

Doe is 7.59 per cent better than average, while Roe is 17.73 per cent below, both intelligible results.

The chief advantage of ascertaining averages by groups lies in the fact that adjustment is thus made for the tendency of one grader to mark high, while another grades low. On a percentage basis all workers are finally equitably compared.

Extending the Scope

Richard's formula also lends itself readily to developing reports to suit different classes of employees. A balanced report can be worked out covering every worker from office boy to president by varying the weights given the different elements to suit the responsibilities of the individual and ascertaining suitable indexes to conform in number to the weightings assigned. The process would be identical to that already worked out. Such a table is suggested in Table 2.

TABLE 2 WEIGHTS ASSIGNED TO ELEMENTS OF RICHARD'S FORMULA FOR DIFFERENT CLASSES OF EMPLOYEES

	M	*T*	*I*	*J*	*Mo*	Total
Worker	4	1	2	1	2	10
Foreman	2	2	3	1	2	10
Superintendent	.	2	4	2	2	10
Manager	.	1	4	3	2	10
Director	.	.	4	4	2	10

Following the Learner's Progress

If the month-to-month percentage which the learner rates is plotted against the theoretical training curve, an interesting and illuminating record is created which far surpasses in usefulness the average record of this nature. Predicted performance is set against actual performance, and the interpretation of deviation is both enlightening and helpful to the instructor or the employer and of distinct moment to the learner. For every abnormal drop or rise there is a reason which challenges discovery by the instructor, and the correct interpretation of the causes of these variations is quite essential to the progress which the individual is making.

Three actual records are given for illustration and study. The first is the record of a normal student in electricity whose graph follows closely the theoretical curve. The second is the record of an unusually capable learner at plumbing whose curve averages 25 per cent better than normal throughout. The third is the picture of a failure at carpentry whose interest did not survive a bare six months, the reasons being lack of home discipline (mother dead), bad companionship, with the usual corollary of dissipation.

Analysis for Training Content

In the light of modern training methods, it seems incredible that for so many years beginners should have been placed in shops and factories to pick up as best they could such information and skill as they might by observing others—"training by absorption." It would be just as reasonable to turn loose a youngster in a university without a definite course of study and expect him to return as a competent lawyer, engineer, or doctor four years hence. Yet that is precisely what has been done with the boy in industry for generations. Industry's course of study is the careful and thorough analysis of the business, trade, or job, broken down into digestible teaching units and regrouped from simple to complex in order to facilitate learning.

Little need be said here about analysis other than to point out that it is essential to the instructor and ofttimes most useful to the executive. The whole panorama of a business—showing the introduction of a new trade term at this point, a danger hazard at that, acquaintance with a new tool or machine here, a necessary mathematical computation or a direct application of a science there, with reasons for everything—offers the thoughtful manager an unexcelled opportunity to review his processes and perhaps to make improvements which might otherwise escape notice. It may also be used to compare the abilities of workmen one with another and to judge their real worth to a business on a definite accomplishment scale.

For the learner the analysis provides the "text book" which must needs be mastered in detail for the information which it contains; it is likewise his "course of study," advancing him

from experience to experience, each progressively more difficult, leading him eventually to the desired goal of competence. The diligent instructor will lose no time in developing his analysis, if he is truly to bear the honored title of instructor.

A Brief Specimen Analysis

Each business demands an analysis to suit, but fundamentally all are alike in that similar operations are grouped together in what is termed a block, the total number of blocks depending on the business. For instance, in a machine shop there would be a lathe block, a planer block, a bench block, a drill-press block, etc. Having determined the blocks involved, each is further broken down into every possible operation, from the simplest to the most difficult and complex job. These will be known as the block units or lessons. These units are further analyzed for their instructional content as to trade terms, safety, science, knowledge of stock, etc. as may be seen from a study of the skeleton lesson plan shown below.

In rearranging the blocks for instructional purposes, no attention is paid to production order. The last production operation will be placed at the beginning if that operation happens to be the most easily learned. The idea held constantly in mind is to facilitate learning; production will follow in due time.

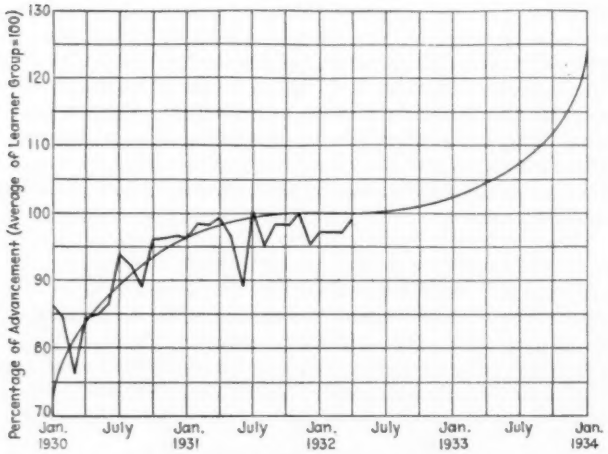

Fig. 4 Training-Progress Graph for Learner of Average Ability

(Showing close approximation to theoretical training curve.)

A sample analysis of patternmaking may be helpful. The patternmaker performs four separate and distinct sets of operations in completing a pattern, as follows:

1 Layout
2 Form and fit
3 Assembly
4 Finish.

Layout (1) and finish (4) are comparatively small blocks. The bulk of his effort is distributed between form and fit (2) and assembly (3). He continually alternates between them until he has built up an object which is called a pattern; hence it is here that one may expect and find the greatest number and variety of learning difficulties.

1 *Layout.* The first step in pattern construction is the preparation of the layout board, on which the object is laid down, full scale, with shrinkage in casting and finish in machining properly provided for trade drawing, pure and simple, with a judicious admixture of trade judgment.

2 *Form and Fit.* From this layout the patternmaker proceeds to the construction of the components making up the pattern. These components take the form of well-known geometrical solids, such as prisms, pyramids, cylinders, cones, etc. each with its frustums; in certain cases, solids of some particular form hand-shaped with the gouge, chisel, etc. are necessary.

This block also brings in most of the woodworking machinery found in the pattern shop, practically all of which is used by the patternmaker in turning out the average product, and it here becomes necessary to provide training on each machine as a part of this block. These are: (1) Band saw, (2) rip saw, (3) cut-off saw, (4) jig saw, (5) jointer, (6) planer, thickness, (7) disk sander,

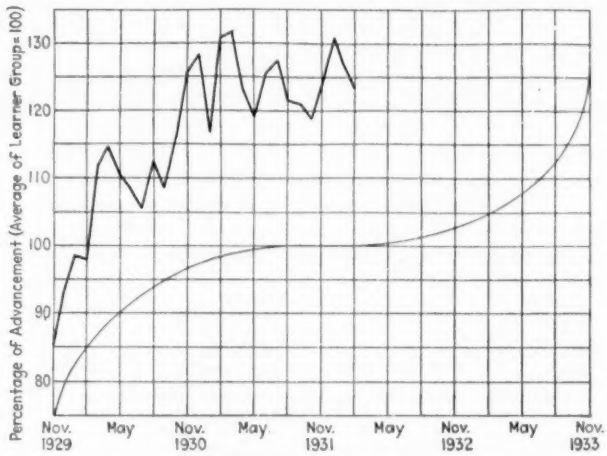

Fig. 5 Training-Progress Graph for Learner of Unusual Ability

(This is 25 per cent better than average throughout.)

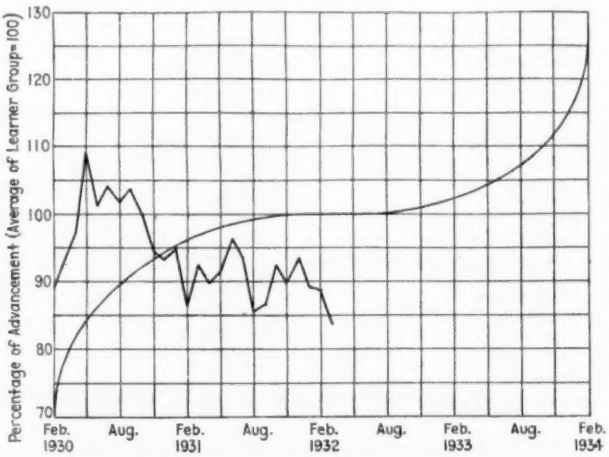

Fig. 6 Training-Progress Curve for Boy Who Failed to Make Good at Carpentry

(Major-trend lines intersect at February, 1931, when boy should have been released.)

(8) spindle sander, (9) turning lathe, (10) Daniels' planer, (11) boring machine.

3 *Assembly.* This is a simple block involving the use of nails, screws, dowels, and glue, and is continuously alternated with the previous block by the patternmaker in making the average product.

4 *Finish.* The reasons for and the proper methods of using sandpaper and shellac are developed.

Rearranged for effective instructional purposes the following order will in general be followed, reverting whenever necessary to blocks already taught to complete the pattern:

Block No. II SKELETON LESSON PLAN Lesson No. 40

TEACHING UNIT: TURNING LATHE: Between Centers, Material Solid, Grain Parallel to Centers

Primary or Secondary: Primary

	STEP 1—PREPARATION:
Idea 1	A piece of wood can be planed to a cylinder
2	It is very difficult to plane it to a true cylinder
3	
4	
5	

J. O. P.: A piece of wood can rapidly be turned to a true cylinder in the lathe

	STEP 2—PRESENTATION:
Point 1	Place material with excess end allowance between centers, screwing up tail stock
2	Turn down to within 1/8" of required diameter with turning gouge
3	Notch to correct diameter with 1/4" chisel, using outside calipers to measure
4	Turn down to notched diameter with flat chisel, using straight edge and calipers for measurements
5	Sandpaper smooth and shellac
6	Remove from lathe
7	Saw to proper length
8	Finish pattern

TYPE JOBS
1. Gate Stick
2. Riser
3. Weight
4. Hammer
5. Bushing
6. Socket

Block No. II AUXILIARY INFORMATION Lesson No. 40

(STEP 2—PRESENTATION)

Teaching Point	TRADE TERMS	SAFETY	CARE OF TOOLS, ETC.	SCIENCE	STOCK
1	Centers Tail stock Parallel			Amount of end allowance	Do not tighten too much or wood will split
2	Turning gouge Rest Calipers	Not to take too heavy a cut	Keep tools sharp.	Proper lathe speed Use of calipers while turning	
3	Notch Small turning chisel	Careful tool does not catch Position of gouge			
4	Large flat turning chisel	Cut must be very light	Keep tool very sharp	If tool is not sharp it will not cut but rub wood off	If tool is not sharp job will be ruined
5		Move rest back to avoid bruising fingers		Very light pressure on sandpaper to avoid changing shape or size	
6					
7		Clamp or brace to avoid rolling when sawing			
8					

FIG. 7 SAMPLE OF A SKELETON LESSON PLAN IN PATTERNMAKING

(Showing complete analysis of unit for instructional purposes and list of jobs typical of operation.)

Block I, finish
Block II, elementary forming
Block III, layout
Block IV, assembly
Block V, assembly forming.

The course of training will then be as follows:

1 Finishing patterns
2 Sharpening tools
3 Boring machine
4 Disk sander
5 Spindle sander
6 Band saw
7 Jig saw
8 Pony or thickness planer
9 Jointer
10 Cut-off saw
11 Power rip saw
12 Daniels' planer
13 Layout
- (*a*) Blueprints
- (*b*) Construction
- (*c*) Shrinkage allowance
- (*d*) Finish allowance
- (*e*) Draft allowance

14 Single-planed objects, no cores
15 Assembly
- (*a*) Nails and screws
- (*b*) Glue
- (*c*) Fillets
- (*d*) Dowel pins

16 Simple assembly of single-planed objects, no cores
17 Cores
- (*a*) Core prints
- (*b*) Core boxes

18 Simple assembly of single-planed objects, cored
19 Turning lathe
- (*a*) Between centers, material solid, grain parallel to centers
- (*b*) Between centers, material split, grain parallel to centers
- (*c*) Assembly between centers, grain at right angle to centers
- (*d*) Assembly, turned to turned, intersection plane or curved
- (*e*) Face plate, material solid
- (*f*) Face plate, material split
- (*g*) Face plate, material built up segmentally
- (*h*) Between centers, material built up in layers
- (*i*) Between centers, material built up in staves
- (*j*) Between centers, long objects, small diameter

20 Single-shaped objects
21 Boxed patterns
22 Skeleton patterns
23 Sweep patterns
24 General shop production.

Experience has shown that two years is sufficient time for the average apprentice to cover thoroughly this entire course, paying his way with salable production all along. Speed follows quickly thereafter, depending upon his natural ability. During the next two years his training curve should turn sharply upward, particularly if the boy has applied himself diligently to the related studies (mathematics, drawing, etc.) in the meanwhile. At completion he stands revealed a craftsman, skilled, intelligent, full of pride in his work and his company, the product of planned training.

CONCLUSION

Thus there has been given a hasty glance at an absorbing field of engineering, that of building with human material. Lack of time and space have precluded a thorough discussion of any of its interesting phases, and many important details have of necessity been omitted altogether. It is hoped, however, that enough has been given to emphasize that a prime necessity of any business is the perpetuation of itself through its personnel, which fact lends to the study of training an ever new and significant aspect.

Discussion

FRANK CUSHMAN.[2] Some of the fundamental considerations for efficiency in a training program which are emphasized in the paper are: (*a*) the proper selection of apprentices and instructors, (*b*) a progressive and systematic series of experiences for apprentices based upon analyses of the trades involved, and (*c*) a practical method of checking the progress of learners and, indirectly, the results of the program.

Perhaps the outstanding characteristic of the scientific method of dealing with any problem is to first secure all of the facts that have a bearing upon it and then to deal with these facts as intelligently as possible. The method outlined in the paper of dealing with a training program and its manifold problems is clearly in harmony with the definition of the scientific method. Many industrial organizations which pride themselves on the applied science reflected in their operations and processes incident to a turning out of their product, fail to appreciate the fact that it is also possible to deal with the problems bearing on the training of workers for their industry, by methods which are equally scientific.

The utilization of Richard's formula in connection with the system of rating apprentices and checking their progress is of particular interest. The writer would question, however, the correctness of assigning fixed weights to all of the factors throughout the period of apprenticeship. In the early stages—say, for the first year or two—the *M* and *T* factors should have maximum emphasis.

While there is no definite agreement as to the significance of the *I* factor in the formula, it is quite widely considered as indicating such things as the ability to comprehend the job in its larger aspects and in relationship to the industry as a whole. That is, at least, one phase of job intelligence. Job intelligence is also, in part, the result of the recognition of the inter-relationships of specific, heterogeneous, and often unorganized technical knowledge which an apprentice acquires on the job as he progresses in his trade. Such being the case, the building up of job intelligence is an important characteristic of the last years of apprenticeship, and it should continue to increase as long as the individual remains alive "from his neck up." This is true for all occupations.

Job judgment is often regarded as the result of the acquirement of skill plus extended experience in utilizing that skill in specific situations. If this idea is sound, the *J* element would have an increasingly larger value as the individual made more and more progress in learning or practicing his trade. For these reasons it would therefore seem that a more nearly correct assignment of weights would place more emphasis upon *M* and *T* in the beginning and an increasing emphasis on *I* and *J* as an individual became more and more expert in the doing of his work. It would seem to be entirely logical, also, that the weights assigned to the *I* and *J* factors would be even higher for a foreman than for a worker.

The morale factor *Mo* is probably one which is of equal importance throughout the career of an individual. It is intended to represent his attitude toward his job and toward his responsibilities as a worker, as well as an individual citizen.

C. F. BAILEY.[3] This matter of hand, head, and heart, this trinity in any young man's personality, is one to which attention is especially called by the author. His emphasis upon it in daily contact is a very practical part of his training program.

This learners' progress curve illustrated in Fig. 1 is also applicable to many of us as we doubtless recall passing through similar experiences, although we probably did not at the time recognize it. It would not be surprising if the author himself, while preparing this paper, might not have struggled along the plateau part of this curve when little progress seemed visible or apparent. The law itself is old even if we may have only lately discerned it. The discovery of this form of the curve applies not only to the students in early training, but it also holds in many of our own later efforts. All the instructors should understand this tendency in order that they may help and encourage the student rather than to yield to the temptation to blame him when at times his efficiency appears to drop.

If any lazy man thinks that he can set up and operate such a training system, he will be woefully disillusioned. It takes intense application, study, work, and perspiration, just as it does for a manager or any other effective executive to carry on in the highest responsible place.

BEN S. MOFFATT.[4] The paper is an excellent statement of some of the fundamentals of training and of a systematic means of measuring its character and progress. Nevertheless, there is one vital fundamental to any program of training with which this author, in common with all of the authors contributing to the subject during the last two decades, has failed to deal, and this is the engineering problem of securing the training operations from the existing work organization within a plant.

It is one thing to establish principles and to delineate fundamentals of an effective program of training, and quite another thing to secure their establishment as an efficient operating function in an industrial plant. A program of training, however carefully and scientifically planned, has still in the long run to prove itself not only effective in training, but also efficient in costs in accordance with the economic conditions regulating the particular plant in which it operates.

During the last decade, many of our boys have been inducted into so-called systems of apprentice training under industrial conditions wherein there did not exist the remotest possibility of securing the fundamentals to training as planned. The conditions existing in some of our plants may in many cases contain all of the elements to the fundamentals as enumerated by the author, and still be unavailable to a training program, owing to the character of their function in the work of the plant and where any attempt to incorporate them into the training program must result in excessive costs and disruption to production schedules, with the inevitable result that in times of economic difficulties this work is the first to be discontinued and wherein in normal times it will be permitted only through an expensive paternalism.

The difficult problem in the field of apprentice training is that of establishing just where, when, how, and to what extent it can be applied effectively in terms of training and efficiently in terms of costs. These two fundamentals to training are purely problems of production engineering.

RENSIS LIKERT.[5] The desirability of a broader training for engineers is being emphasized today in many quarters. The paper emphasizes the use and value of psychology to the engineer, and involves one aspect of the application of psychology to industrial problems.

The "theoretical training-progress curve," which is presented in Fig. 1, is not supported by the curves the author himself

[2] Chief, Industrial Education Service, Federal Board for Vocational Education, Washington, D. C. Mem. A.S.M.E.

[3] Engineering Director, Newport News Shipbuilding and Dry Dock Company, Newport News, Va. Mem. A.S.M.E.

presents and most flagrantly violates an enormous mass of experimental evidence. An almost countless number of experimental studies on the shape of the learning curve have shown that improvement tends to be quite rapid at first, but that with increasing practice less and less improvement occurs, until finally the curve approaches an asymptote which is spoken of as the physiological limit. We all recognize, for example, that in running the 100-yard dash it is relatively easy at first to cut 1/2 second or more off our time, but after we are able to run it in 10 seconds or less it takes a great amount of effort and refinement to reduce our time by as much as one-tenth of a second.

The curve which is generally regarded as best fitting the data from learning experiments is a logarithmic function,[6] although Thurstone[7] claims that it is best fitted by an hyperbolic function.

It is true that in certain instances a plateau does occur in the learning curve. Such a curve is shown in Fig. 10, on p. 125 of Woodworth's "Psychology," revised edition (Henry Holt & Co.). It will be noticed, however, that the plateau is not followed by the type of accelerated improvement shown by Mr. Via's curve, but by another rise showing negative acceleration.

The causes of these plateaus vary. A very frequent cause is a change in the unit with which the learner is dealing. In learning reception in telegraphy the novice first learns to receive letters. After reaching approximately his maximum rate for letters, he then starts receiving in "higher units" or words, and shortly his rate of receiving rises again as he learns to work with these larger units. In addition to "higher units," plateaus may be caused by fatigue on the part of the learner or a shift in interest.

The use of psychological techniques for developing and improving methods for selecting superior or exceptional men for a given job, as the author suggests, is no doubt going to be increasingly used.[8]

The best man for a given job may be, as the author stated, the most intelligent applicant; however, such is not always the case. In many kinds of work too much intelligence is a liability. Experimental studies have shown that in work involving simple, repetitive tasks, intelligent persons often become irritated by the monotony, and they then become a contagious source of dissatisfaction which may spread to other employees. As the author would say, their hearts are unsatisfactory. It is only by the experimental study of each kind of work using proper techniques that we can determine what are the optimum qualifications for that job.

The author's insistence upon "the development of a system of grading which is founded in fact and not on guesswork" is to be commended. It is regrettable, however, that he does not go further in removing the subjective element on the part of the instructor in obtaining the grades. His statement that "no better starting point can be found than that provided by Richards' formula" is to be seriously challenged. Certainly the use of what are commonly known as objective tests are much to be preferred. The latter can be used to reduce considerably, if not entirely eliminate, the subjective element, as represented by the instructor's whims, fancies, and prejudices, in the giving of grades. Even the attitudes of workers toward their work, the company, etc., can be measured quantitatively by the use of recently developed techniques.[9] In judging quality of work and various other factors which must be done by the instructor, the error due to the subjective element may be considerably reduced by the use of carefully constructed rating scales. The techniques used in judging mechanical ability in the Minnesota mechanical ability test study[10] well illustrate the construction and use of devices capable of reducing errors of judgment to a minimum. Such techniques might well be emulated.

If one wishes to analyze the different factors entering into achievement and to determine the relative importance of each factor, this can be done by recently developed statistical techniques. Space does not permit of the discussion of this subject here.

The author's suggestion of plotting the student's progress is to be heartily endorsed. Such use of the learning curve not only informs the instructor of the student's progress, but it is also a powerful motivating device for the student to observe his progress and encourages him to increase his rate of learning.[11]

Author's Closure

The criticism which Mr. Cushman offers to the use of fixed weights in the application of Richard's formula to the progress report has much merit. Undoubtedly each factor has a different rate of development at different points during the training period, and proper allowance should be made therefor. The conclusions which he offers in his discussion of the different factors will enable one to develop a series of reports which should give an accurate picture of learner progress from start to finish.

One of the prime requisites for the success of any training program is the understanding and sympathetic interest of the management. Behind Mr. Bailey's kindly remarks may be discerned the type of managerial attitude which provides inspiration for the successful prosecution of any personnel work, especially training. Without that continued support and encouragement, the best-planned training program must sooner or later fail.

Mr. Moffatt points out that this paper, like others of its kind, does not deal with the problem of securing training operations from the existing work organization within a plant. He submits that apprentices have sometimes been exploited in the past, while on the contrary other training programs have blossomed forth at excessive cost of operation only to wilt at the first economic frost. In these statements the author concurs. A program should not only train, but pay its way as well if it is to be justified.

Perhaps the most potent single influence in a successful and profitable program is the attitude of the management, without whose whole-hearted backing a thousand provocations and obstacles will arise, eventually crushing the sincerest and ablest effort. But when it is understood all along down the supervisory line that the boss expects real cooperation for his training program, it is surprising how smoothly matters will progress. Then if the proved principles of effective training have been adhered to in carrying on the work, and honest purpose has been manifest throughout, the program will prove to be a profitable investment from every angle, including the dollars-and-cents angle. The auditor's cost returns will invariably tell an interesting story. As to meeting production schedules, the interested learner will find a positive delight in holding up his own, as the author can testify from many years of just this type of experience.

[11] Book, W. F., "Psychology of Skill," New York, 1925.

The "theoretical training-progress curve" presented in Fig. 1 is offensive to Mr. Likert, who contends that the preponderance of experimental evidence leans to a hyperbolic or a logarithmic curve instead. In view of the conclusions presented by Mr. L. P. Alford in his excellent paper, "Laws of Manufacturing Management,"[12] there would seem to be a divergence of opinion on this interesting subject, each view being apparently supported by a mass of experimental data. The author confesses to an open mind on the question, although years of observation would incline him to support Messrs. Alford, Bigelow, and other industrial investigators who offer the "plateau between slopes" theory.

It is an accepted principle in psychology that in the process of learning many different connections are established simultaneously. The learner develops aptitudes and attitudes together, and a great deal more is involved in industrial training than the development of mechanical ability alone. This important fact must be taken into account in recording the learner's progress, and will considerably affect the technique of assembling data of this type. This may account for the divergence of opinion which has been noted.

The objection raised to the use of Richard's formula for measuring the progress of the learner is difficult to understand. A grade on workmanship, accuracy, etc., certainly necessitates a critical examination of the day-by-day production of the worker, besides requiring a study of the worker's attitudes as expressed in resourcefulness, interest, etc. The author has not found the use of the objective test method very practical in a busy shop where production schedules must be met regardless, and most assuredly he does not prefer them. Here again there is room for a division of opinion.

It is to be borne in mind that every modern training program reflects an effort to explore and chart that mysterious realm, the human mind, in its relation to physical reaction. Years of patient and careful investigation by our psychologists have thus far produced but few conclusions which may invariably be accepted in toto. Two individuals receive identical stimuli under identical conditions; their responses are altogether different. Why? Conversely, the same response is often observed as a result of different stimuli. Thus it would seem that human behavior yet defies accurate prediction, and beyond a few broad generalities we are still looking hopefully to the psychological laboratories for more light. Much fine work has been accomplished, but much more awaits the future.

It is indeed gratifying to have had these interesting and suggestive discussions offered, and the author is much indebted to each contributor. The wholesome differences of opinion which have arisen should serve to emphasize the need for continued research by both school and shop in this absorbing subject of training.

MAN-55-7

Applications of the Kmh Method of Analyzing Manufacturing Operation

By L. P. ALFORD[1] and J. E. HANNUM,[2] NEW YORK, N. Y.

The kmh method of analyzing industrial operation, first presented by the authors in a paper before this Society in 1928, is used to show variations in size of plants, in length of work periods, and in kmh rates of productivity, value of product, wages, and salaries for four industries in 1929. The trends of kmh operating rates from 1923 to 1931 for 110 concerns are also studied. Important findings are: High wages and high expenditures for supervision accompany high operating performances; the kmh factor is the most convenient unit for measuring plant capacity and a more satisfactory unit for measuring employment and unemployment than a census of workers; the optimum size of plant for most effective production is small; the optimum range of length of work period is considerably shorter than the longest periods that have prevailed currently; changes in productivity are substantially independent of the business cycle; and, due to continuously increasing productivity, the same quantity of product turned out by 50 concerns in a 51-hour week in 1923, could have been produced in a 35-hour week in 1931.

IN A PAPER entitled "A Basis for Evaluating Manufacturing Operation" presented at the December, 1928, Annual Meeting of The American Society of Mechanical Engineers, the authors of this paper developed the kilo man-hour (kmh) method of analyzing industrial operation. The original search was for a base factor which should be: "Measurable by an established unit; universal in use in industry; easy to handle in computation; influential in its effect on industrial operation." The exploration yielded the kmh factor and the method of analysis based upon it. In our 1928 paper we said:

L. P. Alford

J. E. Hannum

> From this base factor, the kilo man-hour, numerous factors of industrial operation can be developed.....It is self-evident that many of these compound factors can be separated into component elements for the purposes of comparison and analysis, but all on the base of the kilo man-hour.
>
> It is evident, likewise, that the results of manufacturing operation expressed in terms of these compound units can be used to compare the period-to-period performance of a single industrial establishment, or to compare the relative achievements of two or more concerns in the same line of industry, or, even as regards certain selected factors, to compare the relative performance of concerns in different lines of manufacturing.

Work on applications of the method has been carried forward during the past four years. A sufficient number of data have now been accumulated to warrant the preparation of this paper, to show further details of the method, and to give certain results obtained and conclusions reached.

The material available has had two origins:

1. In a research into the factors in, and measurement of, technological unemployment made by the authors for the American Engineering Council
2. In a statistical analysis of certain data for four industries presented in a special industrial study of the United States Bureau of the Census.

These data in each instance represent a substantial assay of the fields investigated. The number of employees in the manufacturing concerns reporting to the American Engineering Council is $^1/_{63}$ of the total number employed in 1929, while the number of railroad employees is $^1/_{33}$ of the total number employed in 1929; the data in the industrial study of the Bureau of the Census were reported for 95 per cent of all the value of products for three industries, and for 25 per cent in the fourth. The extent of the assays and the origin of the data give them a high degree of credibility.

Several general findings are supported by the facts brought out by the studies:

1. The ranges of productivity, selling value of product, and value added by manufacture, are wider than those revealed by the study of 1928
2. The operating factors are of the same order as those revealed by the study of 1928

---

[1] Vice-President, Ronald Press Company. Mem. A.S.M.E. Mr. Alford received the degrees of B.S. (1896), M.E. (1905), and Dr. of Eng. (1932) from Worcester Polytechnic Institute. He was production superintendent, McKay Shoe Machinery Co., 1899–1902; mechanical engineer, United Shoe Machinery Co., 1902–1907; engineering editor, 1907–1911, and editor-in-chief of *American Machinist*, 1911–1917; editor, *Industrial Management*, 1917–1920, *Management Engineering*, 1921–1923, and *Manufacturing Industries*, 1923–1928; and consulting editor, *Factory and Industrial Management*. He is the author of "Management's Handbook" (1924); and "Laws of Management" (1928). He served on committees of the American Engineering Council which produced reports on "Waste in Industry," 1922; "Twelve-Hour Shift in Industry," 1922; "Safety and Production," 1927; and "Recent Economic Changes," 1928. He is past vice-president, American Engineering Council; past-president, Institute of Management; past vice-president, A.S.M.E.; and a member of numerous allied societies. He received the Melville Medal in 1927 and the Gantt Medal in 1931.

[2] Editor, The Engineering Index, The American Society of Mechanical Engineers. Assoc-Mem. A.S.M.E. Mr. Hannum received degrees of B.S. (1915) and M.E. (1920) from Pennsylvania State College. He was machine-shop foreman, Skinner Engine Co., 1915–1916; instructor in industrial management, Purdue University, 1916–1918; industrial engineer, Diamond Chain and Manufacturing Co., 1918–1919; in charge of industrial education of service men blinded in the World War, Red Cross Institute for the Blind, 1919–1922; research engineer, Eyesight Conservation Council, 1923–1929; director, Safety and Production Study, American Engineering Council, 1926–1927; editor of The Engineering Index since 1927, and office manager of A.S.M.E. since 1931. He is also a member of the American Academy of Political and Social Science, the A.A.A.S., American Management Association, Illuminating Engineering Society, and the Institute of Management.

Contributed by the Management Division and presented at the session on Thursday, December 8, of the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

3 High wages are shown to accompany high operating performance

4 High expenditures for supervision are shown to accompany high operating performance

5 The kmh factor is shown to be a more satisfactory unit to use in measuring employment and unemployment than the data from a census of workers

6 The kmh factor is shown to be the most convenient unit to use in measuring and comparing plant capacities

7 The optimum size of plant for most effective production is small when indicated by kmh worked per year or number of workers. The ranges for four industries studied follow. The relation between kmh and number of workers is on the basis of 2000 working hours per man per year.

Industry	Optimum number of kmh	Optimum number of workers	Percentage of total kmh in optimum range
Blast-furnace operation..	270–640	135–320	33.8
Machine-tool building....	30– 80	15– 40	4.5
Petroleum refining.....	40–140	20– 70	7.7
Lumber manufacturing...	50–300	25–150	15.2

8 The optimum range of length of work period for most effective operating performance varies considerably among the four industries studied. The upper limit in each range is substantially lower than the highest values that have prevailed currently. The lower limit for three industries is substantially the 35-hour-per-week schedule referred to in item 11 following. The ranges for this factor are given in a tabulation below.

Industry	Optimum range of length of year in hours	Optimum range of length of week in hours	Percentage of total kmh in optimum range
Blast-furnace operation...	1810–2610	34.8–50.2	26.5
Machine-tool building.....	1930–2460	37.1–47.3	40.9
Petroleum refining.....	2450–2810	47.0–54.0	72.2
Lumber manufacturing....	1600–2640	30.8–50.8	64.0

9 Changes in productivity are substantially independent of conditions established by the expansion or recession of business activity, or of the operation of the business cycle

10 A majority of the manufacturing concerns reporting, 58 per cent, had a higher rate of productivity in 1931 than in 1928. The increase in productivity for 1928 over 1925 ranges from 1.3 to 83.5 per cent; and for 1931 over 1928 is 0.5 to 112.2 per cent

11 The concerns which showed a continuous increase in the kmh rate of production from 1923 to 1931 reduced, on an average, the number of kmh per unit of product by 31 per cent. That is, if the working force of 1923 had remained unchanged, the amount of product turned out in a 35-hour week in 1931 would have been the same as was produced in a 51-hour week in 1923

12 The railroads that reported showed a reduction in kmh per unit of service of 33 per cent from 1923 to 1931.

Measurement of Operating Performance

In a report submitted to the Committee on Technological Employment of the United States Department of Labor by the Committee[3] on Man-Hour Information of the American Engineering Council, in September, 1931, there were proposed certain units for measuring operating performance, each being a rate computed from some two of four records of industrial operation. The four quantities are:

A Average Number of Workers Employed
B Total Number of Man-Hours Worked
C Total Quantity of Product Output
D Total Number of Workers Employed.

Eight significant units of measurement may be derived from these four quantities:

1 Employment Unit: Number of kilo man-hours worked per year ($B \div 1000$). The trend of this unit indicates directly an increase or a decrease in time employment, and is therefore a quantitative measure of employment

2 Productivity Unit: Quantity of product output per kilo man-hour ($C \div$ kmh worked). The trend of this unit indicates an improvement or recession in industrial effectiveness, inasmuch as it is an integration of the energies affecting operating performance

3 Working-Force-Requirement Unit: Average number of workers per kmh ($A \div$ kmh worked). The trend of this unit indicates an increase or a decrease in the number of workers required to perform 1000 hours of work in a year

4 Labor-Utilization Unit: Average number of workers per unit of product output ($A \div C$). The trend of this unit indicates the influence of labor-saving facilities in the saving or wasting of human energy

5 Labor-Performance Unit: Quantity of product output per worker ($C \div A$). The trend of this unit indicates the effectiveness of the working force

6 Labor-Time Unit: Number of man-hours worked per worker ($B \div A$). This unit measures the length of the working period, and the trend indicates fluctuations in the length of the working period

7 Time-Utilization Unit: Number of man-hours worked per unit of product output ($B \div C$). The trend of this unit indicates the influence of time-saving facilities in saving or wasting time

8 Labor-Stability Unit: Total numbers of workers per kmh ($D \div$ kmh worked). The trend of this unit indicates the effectiveness of managerial skill in handling personnel.

Productivity and Employment

The production and man-hour data gathered by the American Engineering Council for the Safety and Production Study in 1926 are so admirably suitable for analysis by the kmh system that the records of 110 companies have been brought up to date by the accumulation of additional data through 1931. These data have been used by the authors in the preparation of a report on technological unemployment recently submitted to the American Engineering Council showing the trends of the eight units for the 110 companies. The value of the kmh system in analyzing operating results is indicated by the discussion of employment, productivity, and working hours that follows.

Measure of Employment. The authors have contended that the number of kmh worked and not the average number of workers employed is the correct measure of the trend of employment.[4] Reports from 110 concerns support this contention. The aggre-

gate number of 414,671 kmh worked in 1928 was reduced by 129,533 kmh to 285,138 kmh in 1931, a reduction of 31.3 per cent. Wide differences exist between the percentages of the decreases in the number of kmh worked and the percentages of the decreases in the number of workers employed. The percentages of decrease in the number of kmh worked are, for the majority of companies, much greater than the percentages of decrease in the number of workers employed. The latter are greater than the former for but seven companies; the two decreases are the same for but three companies. The frequency of the ratios, shown in Fig. 1, indicates the wide range of differences between the decreases of the two quantities, the ratio being more than 4 to 1 for eleven companies.

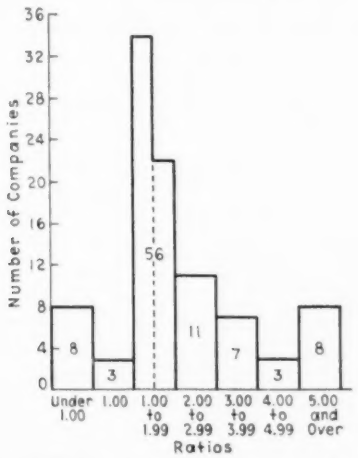

FIG. 1 RATIOS OF DECREASES IN THE NUMBER OF KILO MAN-HOURS WORKED TO DECREASES IN THE NUMBER OF WORKERS EMPLOYED BY 96 COMPANIES, FROM 1928 TO 1931

The character of the quantitative values and relationships is indicative of the unreliability of the number of workers employed as a measure of employment. Variations in the length of the work day and the work week, which are entirely ignored by using the number of workers, are correctly accounted for when the number of kmh worked is used as the evaluator of employment.

Decrease in Employment. During the three-year period from a peak year of prosperity, 1928, to a low year of depression, 1931, decreases in the number of kmh worked range from 1.4 to 86.5 per cent. Only 13 of the 110 companies increased employment; 72 per cent decreased employment from 20 to 70 per cent; the decrease for 9 companies has been from 70 to 90 per cent. (See Fig. 2.)

Increase in Productivity. During a period of depression when employment is being decreased by laying off the less efficient workers, productivity increases at high rates in well-managed plants. Production records of 110 companies from 1925 to 1931 are used to indicate quantitatively the accuracy of this statement.
